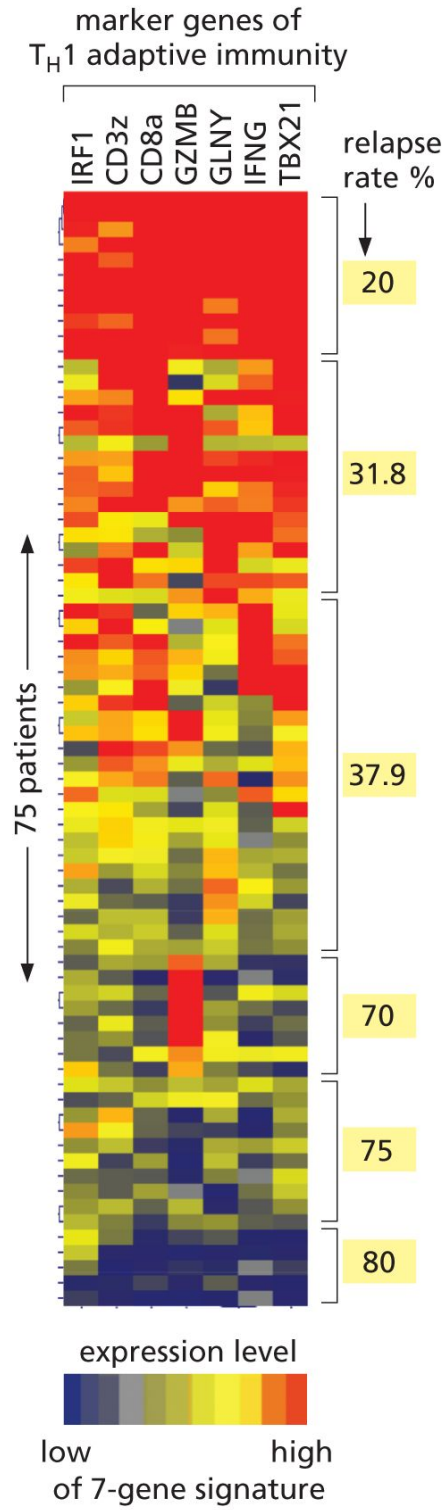
A breakdown of how six different categories of C D45 positive immunocyte cells are represented in four different types of tissue, both normal and cancerous. The six immunocyte categories are C D3 positive C D4 positive T cells; C D3 positive C D8a positive T cells; C D19 positive C D20 positive B cells; C D14 positive myeloid cells; C D13 positive myeloid cells; and other CD45 positive cells. In three samples of invasive ductal carcinoma breast cancer, C D3 positive C D4 positive T cells constituted almost 40 percent of all C D45 positive cells, compared to 15 percent in two adjacent normal tissue samples. The percentage of C D13 positive myeloid cells was less than 10 in the cancerous tissue, compared to more than 20 in the normal tissue. In 23 samples of non-small-cell lung cancer, C D3 positive C D4 positive T cells constituted 40 percent of all C D45 positive cells, compared to 30 percent in 23 adjacent normal tissue samples. The percentage of C D19 positive C D20 positive B cells was about 15 in the cancerous tissue, compared to 5 in the normal tissue. In 10 samples of esophageal carcinoma, C D14 positive myeloid cells constituted 15 percent of all C D45 positive cells, compared to less than 5 in 10 adjacent normal tissue samples. The percentage of C D19 positive C D20 positive B cells was about 10 in the cancerous tissue, compared to more than 20 in the normal tissue. Finally, in 14 samples of malignant pleural mesothelioma, C D14 positive myeloid cells

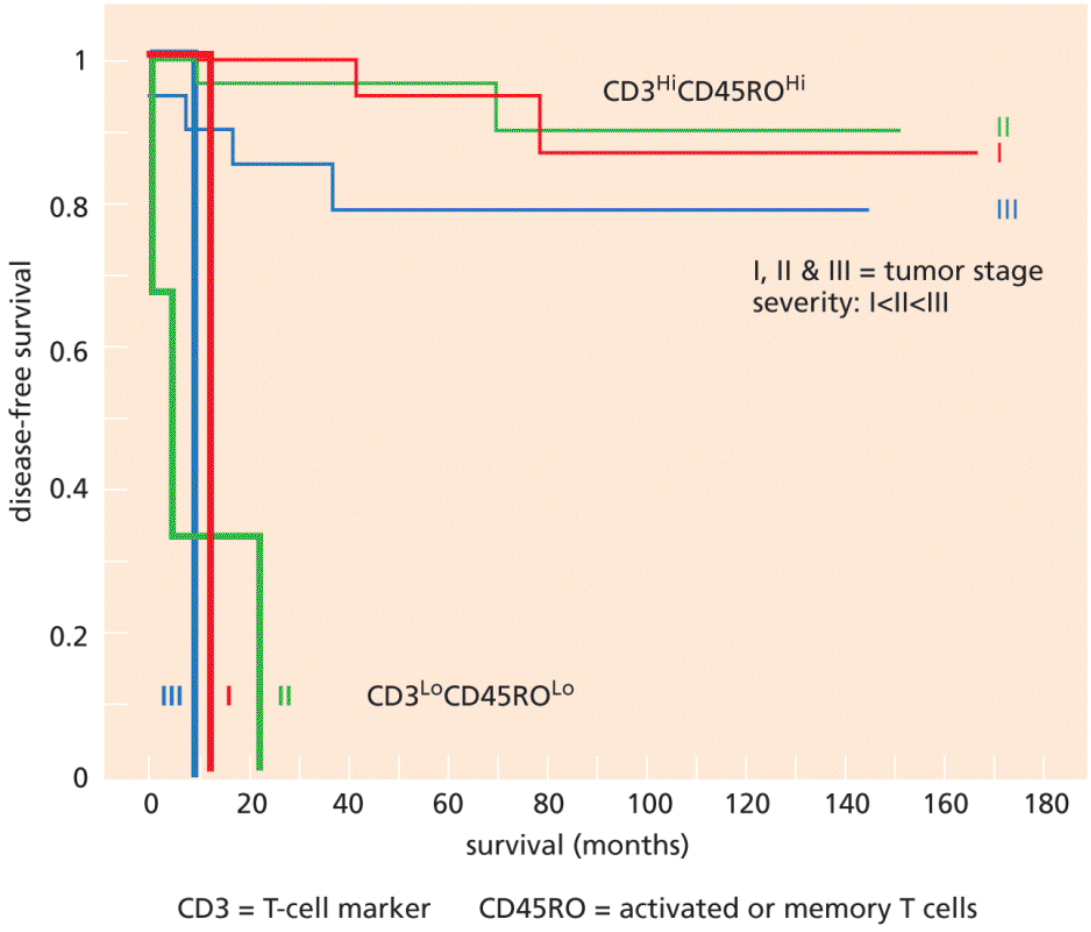
constituted 40 percent of all C D45 positive cells, compared to about 25 in 4 normal pleura samples. The percentage of C D13 positive myeloid cells was about 15 in the cancerous tissue, compared to almost 50 in the normal tissue.

Figure 15.4 Tumor-specific infiltration by immunocytes Analysis of immunocyte populations present in different tumors shows dramatic differences among the immune cells recruited by these various tumors. In the analyses presented here, normal and tumor tissue samples excised from patients were enzymatically digested; single cells in the resulting suspensions were then detected with dye-labeled monoclonal antibodies and analyzed by flow cytometry. Only those cells expressing CD45, an antigen present on all leukocytes, were included in these analyses. The number (*N*) of each tumor type and corresponding normal tissue samples analyzed is given above the bars; in each case, normal adjacent tissue (adj. normal) was analyzed in parallel with tumor samples (T) with the aid of fluorescently labeled antibodies specific for each of the indicated displayed cell-surface antigens: CD3, a component of the TCR complex found on all T cells; CD4, helper T cells, and regulatory T cells; CD8, cytotoxic T lymphocytes; CD13, many myeloid cell types, including granulocytes and monocytes; CD14, monocytes and macrophages; CD19, B cells; CD20, B cells. (Courtesy of L.M. Coussens.)



A graphic depicting the expression levels of 7 marker genes of T H1 adaptive immunity in 75 patients, ordered by relapse rate, from 20 percent to 80 percent. The analysis clearly shows that the higher the expression levels, the lower the relapse rate.

(A)



A line graph displaying the percentage of patients that survive disease-free, as a function of time, for six different patient groups, each characterized by stage of cancer and by the presence or absence of T cells. Of the C D 3 Hi C D 45 R O Hi patients, 80 percent survived disease free up to at least 140 months, even patients with stage 3 cancer. Of the C D 3 Lo C D 45 R O Lo patients, none survived disease-free past 22 months.

(B)

Figure 15.5 T-cell infiltration and the course of colorectal carcinoma progression (A) The clinical course of colorectal (CRC) tumor progression was monitored in a group of 75 patients over periods up to 15 years and correlated with the presence of specific subtypes of immunocytes in their tumors. Whole tumors, encompassing both their epithelial and stromal compartments, were analyzed for their patterns of RNA expression, using qRT-PCR. An expression signature composed of seven genes (*top*) was generated in order to gauge

specifically the representation of immune cells that had infiltrated colorectal carcinomas and also expressed genes of the T_H1 subset of helper T cells, specifically memory T cells. These cells persist for many years after exposure to antigen and can be reactivated quickly in response to a subsequent challenge by this antigen. Those patients whose tumors carried many cells having high expression of this set of T_H1 markers (*top*) experienced a vastly lower rate (20%, *right side*) of post-surgical relapse (generally liver metastases) than did those whose tumors contained low levels of such T cells (80%, *bottom*). (B) An even more dramatic correlation between T-cell infiltration and clinical progression came from analysis of a group of 406 CRC patients, who were stratified into four subgroups according to the stage of histopathological progression of their primary CRC tumors, with stage I tumors representing the least aggressive and stage IV representing the most aggressive subtype. Each tumor was analyzed for the presence of $CD3^+$ (overall T cells) and $CD45RO^+$ (memory T cells) both at the invasive margins of tumors and at the centers of such tumors. As the Kaplan–Meier curves illustrate, most stage I, II, and III tumor patients showed long-term survival if observation revealed that their tumors exhibited high levels of CD3-positive and CD45RO-positive cells at both the tumor centers and invasive margins, whereas those patients whose tumors lacked such T cells in both sites declined precipitously after initial surgery. The clinical progression of stage IV patients, almost all of whom did poorly, is not shown here. (From J. Galon et al., *Science* 313:1960–1964, 2006. With permission from AAAS.)

The evidence presented in Figure 15.5 points to apparently important roles of subsets of T lymphocytes in controlling colorectal carcinoma progression; similar evidence exists for other carcinoma types as well. In addition, the phenotypic state of the cancer cells within a tumor may exert strong influence on the spectrum of immunocytes in its stroma. As one example, the carcinoma cells within a tumor will attract quite different groups of immunocytes, depending on whether these individual neoplastic cells reside in the epithelial or mesenchymal phenotypic states that are described in Section 13.3 and, in more detail, in Chapter 14.

As we will see in this chapter, considerable progress has been made in uncovering some of the mechanisms by which the immune system recognizes and responds to, or fails to respond to, cancer. At present, this knowledge is still incomplete and the underlying mechanisms remain imperfectly understood.

OceanofPDF.com

Glossary

immunocompromised
: Describing an organism lacking a fully functional immune system. *Also termed* **immunodeficient**.

acquired immunodeficiency syndrome
: Disease caused by infection with human immunodeficiency virus (HIV) that causes depletion of CD4+ lymphocytes and resulting collapse of adaptive immunity.

allogeneic
: Referring to a pair of tissues or associated cells that differ genetically and, quite possibly, antigenically.

histoincompatible
: Failure of tissues or cells to be tolerated by the immune system of the host organism into which they have been engrafted. *See also* **histocompatible**.

immunocyte
: A cell associated with one of the multiple types of cells that form the functional arms of the immune system.

lymphocytes
: Class of leukocytes that mediate humoral or cellular immunity, encompassing B cells, T cells, and NK cells and derivatives thereof.

opportunistic
: A process, such as an infectious event, that exploits an environment that normally would be inhospitable to that process. An opportunistic infection by a virus occurs in host organisms that have compromised antiviral defense mechanisms.

debulk
: To reduce in overall size with the intent of removing the great majority of a mass such as a solid tumor.

15.3 The immune system functions to destroy foreign invaders and abnormal cells in the body’s tissues

The structures of our tissues clearly provide physical barriers and thus a measure of protection against infections by various pathogens. Beyond these barriers, immune systems developed early in metazoan evolution in order to defend against infections by viruses, bacteria, and fungal parasites. In vertebrates like ourselves, this protection is implemented by the diverse cellular components of the immune system, including lymphocytes, macrophages, neutrophils, dendritic cells, and natural killer (NK) cells as described below.

Vertebrate immunity is mediated by two distinct but interacting physiologic systems, the innate immune system and the adaptive immune system. **Table 15.1** summarizes some of the salient features and differences in these two systems. Most fundamentally, the innate immune system recognizes molecular patterns characteristically associated with pathogens and some cancer cells and responds with a variety of measures to prevent, limit, or eliminate infections and to eliminate incipient tumors as well. Such innate immunity operates “instinctively,” that is, without any prior exposure of an individual organism to such pathogens, cancer cells, and their associated antigens; accordingly, this type of immunity is not learned during the lifetime of the individual, but instead exists constitutively, being orchestrated entirely by genes inherited through the germ line.

Table 15.1 Innate and adaptive immunity

Property	**Innate immunity**	**Adaptive immunity**
Phylogenetic distribution	All phyla	Demonstrated only in vertebrates and in bacterial species endowed with CRISPR
Receptor diversity	Many types of germ-line-encoded receptors,	Antigen receptors including antibodies and T-cell

Property	Innate immunity	Adaptive immunity
	but little or no diversity within each receptor type	receptors encoded by genes that arise from somatic diversification of germ-line genes to generate an exceedingly large diversity of antigen receptors
Specificity	Molecular patterns	Highly specific. Can discriminate subtle differences between molecular structures. Each member of a species is capable of recognizing $>10^7$ antigen specificities.
Immunological memory	Generally absent, but some cells of the innate immunity system may show increased responses to subsequent encounters with the same stimulus	Capacity for more rapid and more potent immune responses to subsequent encounters with the same antigen
Self/non-self discrimination	Excellent discrimination of microbial molecular patterns from host molecular patterns	Very good but imperfect. Failures can occur and result in autoimmune disease.
Major soluble components	Antimicrobial peptides and proteins, cytokines, chemokines, and other soluble mediators including complement proteins	Antibodies, cytokines, and chemokines

Property	Innate immunity	Adaptive immunity
Major cell types	Many different types of phagocytes including macrophages, neutrophils, dendritic cells; NK cells; some epithelial cells	T cells, B cells, and antigen-presenting cells (primarily dendritic cells, but in some cases, activated macrophages and B cells)

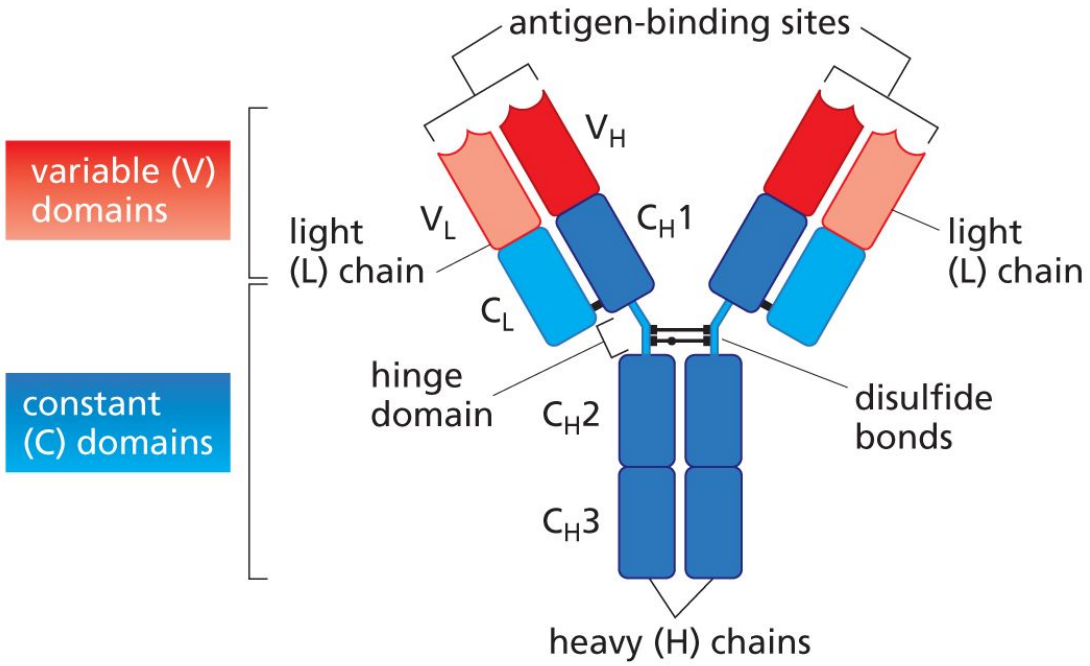
This innate behavior contrasts with that of the adaptive immune system, whose actions are indeed triggered by exposure to a given antigen or the antigens borne by an infectious agent or by aberrant cells, including cancer cells. The learned behavior of the adaptive immune system often enables an individual to respond quickly and strongly to subsequent challenges posed by exposure to the same antigens or infectious agents years or decades later. Such delayed responses are indicative of immunological memory, that is, the ability of the adaptive immune system to “remember” over extended periods of time the prior exposure to an antigen or set of antigens.

The innate immune response can be construed as the first line of defense against attacks launched by pathogens, because its components preexist in the body and therefore largely do not require an extended period of development. The second, more powerful line of defense is ultimately afforded by the adaptive immune response, which is highly specific for the antigen-displaying targets that it recognizes and undertakes to attack. Moreover, the adaptive response to these targets can undergo great amplification and is capable of recognizing the essentially unlimited diversity of molecular structures, which are the physical embodiments of antigens.

Strikingly, after an initial encounter and response to a given novel antigen (or antigen-displaying cell), subsequent adaptive immune responses to that particular antigen are typically far stronger and more rapid in onset than the initial response. These secondary responses, sometimes occurring months and even years after the initial exposure to an infecting pathogen or foreign antigen, reflect the phenomenon of immunological memory cited above and are the basis of vaccination. Thus, lymphocytes that participated in a successful immune response to an initially encountered infectious agent (or tumor cell) and associated antigens will leave behind descendants that will persist in the body for years or decades and confer ongoing protection against subsequent exposure to this agent. It is these long-lived lymphocytes that preserve the record of initial encounters with an antigen and therefore provide the immunity conferred by vaccination.

Two classes of lymphocytes, T lymphocytes (T cells) and B lymphocytes (B cells) and their products, are the cellular mediators of adaptive immunity. B cells produce antibody molecules (also known as immunoglobulins) and T cells are key effectors and regulators of immune responses. Distinct classes of antigen-specific receptors displayed on the surface of a T cell—T-cell receptors (TCRs)—and on the surface of a B cell—B-cell receptors (BCRs)—endow these lymphocytes with the ability to recognize the particular molecular configurations of antigens, doing so with exquisite specificity. In addition, many of the soluble antibody molecules secreted by B cells and present in our blood exhibit high specificity for recognizing and binding tightly to their cognate antigens, that is, the antigens that previously provoked their formation. The B-cell receptors displayed at the cell surface by B lymphocytes are membrane-bound versions of the soluble antibody molecules that these cells secrete.

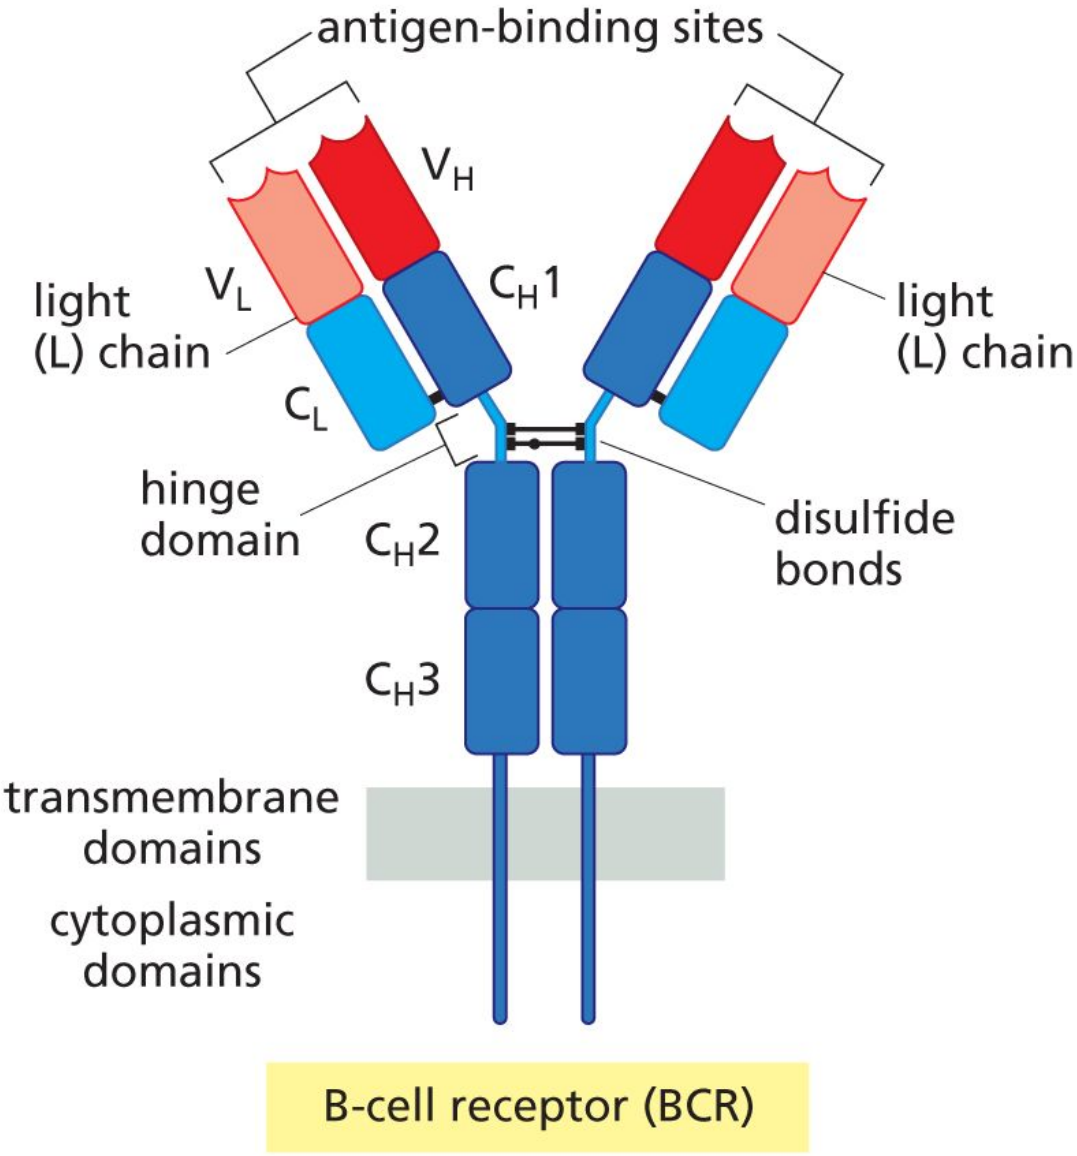
The functions of these various membrane-bound and secreted antigen-recognizing proteins, or antibodies, can be understood from **Figure 15.6**, which reveals that these antigen-recognizing immune molecules contain subdomains domains known as variable regions (V regions), which are the sites of their antigen-recognizing and antigen-binding functions. V regions are composed of amino acid sequences that vary according to their antigen specificity, allowing them to recognize and bind an extraordinarily diverse array of antigens. In effect, V regions carry the antigen-binding sites that recognize and bind antigen molecules having complementary structures, much like the fit of individual keys (antigens) in appropriate cognate locks (V regions).



antibody molecule

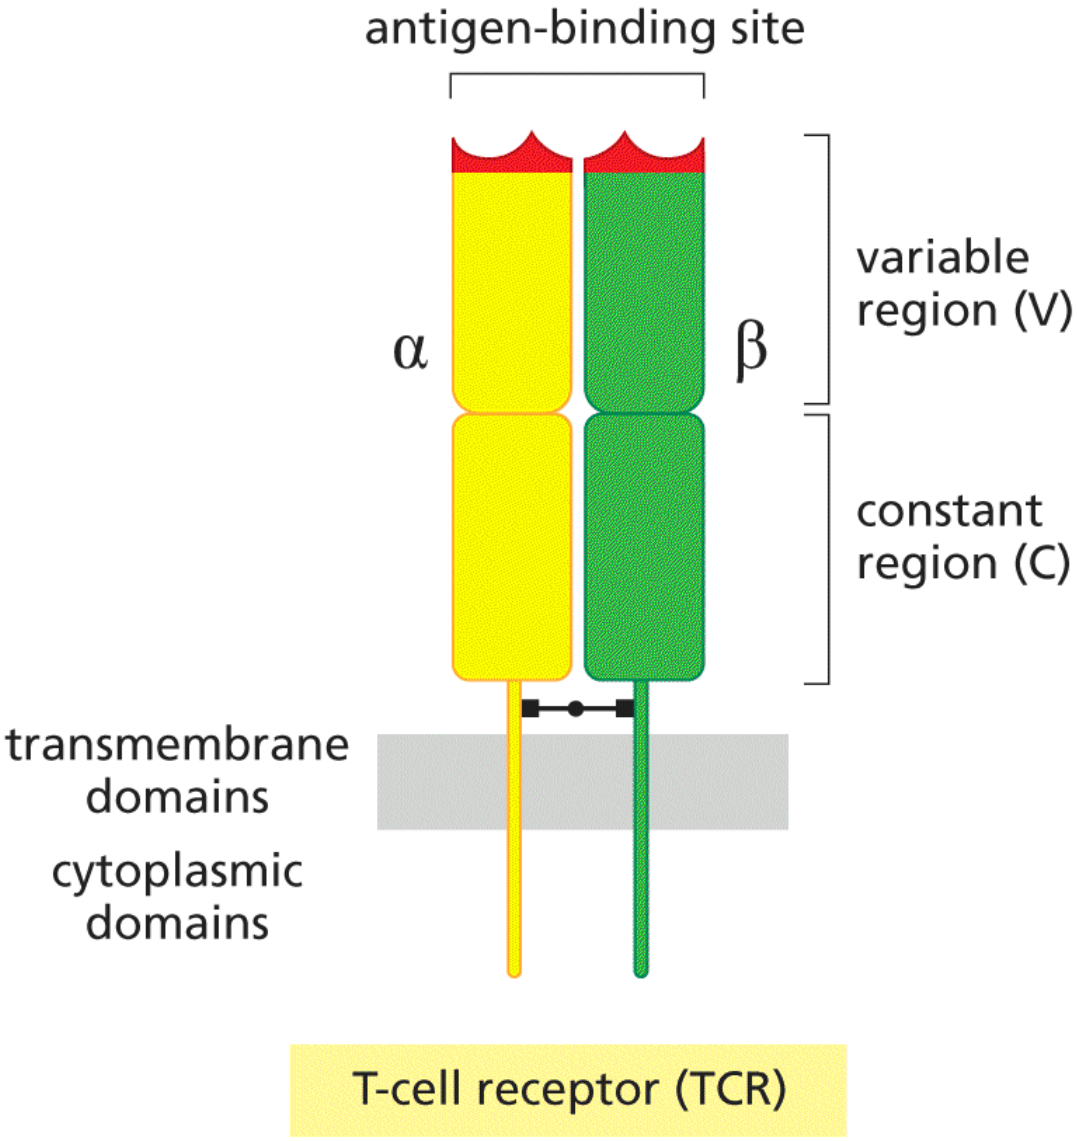
A Y-shaped antibody molecule, with disulfide bonds connecting the left and right halves at the hinge domains. The vertical portion below the linked hinge domains consists of two parallel heavy chains, each consisting of a C H 3 domain beneath a C H 2 domain. Each of the two angled arms above the linked hinge domains consists of a heavy chain on the inside, toward the midline, and a parallel light chain on the outside, away from the midline. The heavy and light chains in the arms each have a constant domain on the hinge end and a variable domain on the free end. These are labeled C H 1, C H L, V H, and V L, respectively. The antigen binding sites are on the free ends of the variable domains.

(A)



A B-cell receptor, or B C R. The structure is the same as that of an antibody molecule, except that the C H 3 domains have long, thin tails, consisting of transmembrane domains and cytoplasmic domains that penetrate through a plasma membrane into cytoplasm.

(B)



A T-cell receptor, or T C R, consists of alpha and beta monomers brought together. Each monomer has a variable region up top, where the two ends together form the antigen binding site, and a constant region down below, where long, thin tails, consisting of transmembrane domains and cytoplasmic domains, penetrate through a plasma membrane into cytoplasm.

(C)

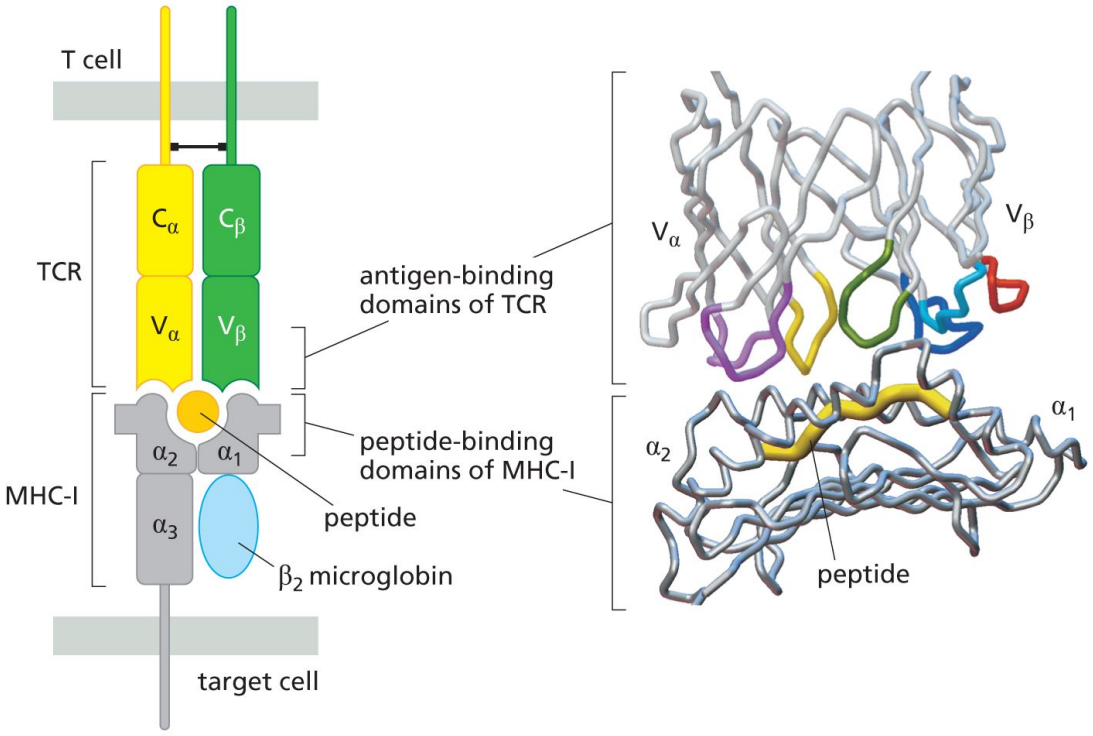
Figure 15.16 Checkpoint inhibition of T-cell activation and effector function
Checkpoint controls ensure the limiting or shutdown of the T-cell response and operate in two successive phases of response development. (A) Activation phase. A naive T cell is primed within a lymph node by engagement of its TCRs with cognate peptide:MHC-I complexes presented by a dendritic cell (DC) (*left*). The

essential co-stimulation that is necessary to augment signaling from the TCR into the T cell is provided by engagement of the T cell's co-stimulatory receptor, CD28, with stimulatory ligands (CD80/86) displayed on the surface of the dendritic cell (*inset, above*). The combined strength of these signals is sufficient to force activation of the naive T cell, causing it to undergo proliferation and develop effector functions. An alternative counteracting response occurs when the CTLA-4 receptor of a T cell, rather than its CD28 receptor, binds to CD80/86 of a dendritic cell: rather than stimulating the T cell and causing its activation, this CTLA-4:CD80/86 binding generates signals that inhibit T-cell activation (*inset, below*). CTLA-4 binding to the CD80/86 ligands is stronger than is CD28 binding; hence, the inhibitory effects of CTLA-4 dominate if both are expressed. As the activation of T cells mediated by CD28 proceeds, the levels of CTLA-4 increase progressively, ultimately ensuring the shutdown of further CD28 signaling and resulting T-cell activation. Those T cells that undergo successful activation leave the lymph node via the circulatory system and are carried to peripheral tissues. This negative-feedback control of T-cell activation operates independently of the T_{reg} inhibition described in Figure 15.15. (B) Effector phase. Those CD8 T cells that are successfully activated by antigen exposure (*broad blue arrow*) are exported from the lymph node and disperse into peripheral tissues, in this case a tumor (*right*). There they enter the tumor microenvironment (TME), where recognition of peptide:MHC complexes displayed by cancer cells can provoke a cytotoxic attack by the activated CD8 T cells. However, the presence of PD-1, an inhibitory receptor also displayed on the surface of the cytotoxic CD8 cells, renders them susceptible to inhibition if they happen to encounter the inhibitory ligands PD-L1 or PD-L2 (PD-L1/2) displayed either by cancer cells or by other noncancerous bystander cells present in the TME (*inset*). (Adapted from R.J. Lee, J.S. Abramson and R.A. Goldsby, Case Studies in Cancer. New York: W. W. Norton & Company, Inc., 2018.)

In addition, TCRs and BCRs, like antibody molecules, contain constant regions (C regions) that differ little between different molecules of a given class. Thus, the C regions of a diverse array of TCRs contain amino acid sequences that are identical or similar to one another; the same can be said of BCRs and their antibody counterparts. In effect, the constant regions represent the structural scaffolds required for the multiple functions of these three classes of immune molecules—secreted antibody molecules, TCRs, and BCRs. As should be apparent, the C regions of these molecules are not involved in antigen recognition.

Although all three classes of molecules are members of the same immunoglobulin superfamily of proteins, TCRs, BCRs, and antibodies differ markedly from one another in certain critical structural features. As an example, while T-cell receptors are

heterodimers, the basic structure of antibodies and BCRs can best be described as dimers of identical heterodimers. Thus, as illustrated in Figure 15.6, each heterotetramer forming an antibody molecule is composed of four immunoglobulin chains, two identical larger heavy chains (H) and two identical smaller light chains (L). Note that when antibody molecules remain anchored to the surfaces of B cells that made them, they function as antigen-recognizing, B-cell receptors (BCRs). When present in soluble, secreted form, the almost-identical immunoglobulin molecules are referred to as antibodies and are found throughout the blood, lymph, and tissue fluids. In contrast to antibodies and BCRs, the antigen receptors found on most T cells recognize a complex formed between an antigen-derived peptide and an MHC protein, a type of cell surface molecule known to be encoded by the major histocompatibility complex of genes for which they are named (**Figure 15.7**); they will be discussed in detail in Sections 15.5 and 15.6.



An illustration of an M H C-1 complex binding to a T cell receptor to connect a T-cell and a target cell. The two tails of the T cell receptor penetrate the plasma membrane and cytoplasm of the T-cell. The one tail of the M H C-1 complex extends from the alpha 3 component into the plasma membrane and cytoplasm of the target cell. The head of the M H C-1 complex consists of an alpha 1, an alpha 2, and a peptide; this combination constitutes the peptide-binding domain of M H C-1. It binds to the antigen binding site of the T cell receptor. Also present is a beta 2 microglobin; it is attached to the back of the alpha 2. Also shown is a

ribbon diagram representation of the interacting binding domains of the T cell receptor and the M H C-1 complex.

Figure 15.7 T-cell receptors are specific for a complex of peptide and MHC T-cell receptors (TCRs) recognize the structure formed by the noncovalent interaction of a peptide (*yellow*) with the binding pocket of an MHC-I or MHC-II molecule. An MHC-I complex is illustrated here (*left*). Displayed here is the recognition of such a complex (i.e., a peptide in the cleft formed together with the peptide-binding domains of an MHC-I molecule) by the αβ TCR of a T cell. The structures (*right*) of the polypeptide backbones of a TCR antigen-binding domain (*above*) bound to an MHC-I molecule and its associated bound peptide (*below*) complex has been determined by X-ray crystallographic analysis. (Adapted from K. Murphy and C. Weaver (eds.), Janeway's Immunobiology, 9th ed. New York: Garland Science, p.162, Figure 4.24; ribbon diagram from K.C. Garcia, et al. *Science* 274:209-219, 1996. With permission from AAAS.)

The binding of antigens to the antigen-binding sites of TCRs or BCRs triggers adaptive immune responses. Although antigen binding is necessary to trigger an adaptive immune response, it is almost never sufficient. As a rule, the immune system must receive additional signals in order to assemble a biological program that permits the successful initiation of an actual adaptive immune response. Whether or not an antigen can function as an immunogen, that is, a substance capable of provoking an immune response, depends on the context of the encounter with this substance. As we will see, a major problem of anti-cancer immunotherapies derives from the difficulty in rendering cancer cell-associated antigens immunogenic, that is, creating the conditions that make a cancer antigen an immunogen and thus capable of provoking an effective immune attack.

OceanofPDF.com

Glossary

immunological memory
: The process by which cells of the adaptive immune system store information of an encounter with an antigen and exploit this stored information to rapidly mount a second immune response against this antigen long after the initial encounter with the antigen has taken place.

immunoglobulin
: An antibody molecule assembled from two heavy and two light chains.

T-cell receptor
: The immunoglobulin-like molecule that is displayed on the surface of T cells and used by them to recognize antigens displayed by HLA/MHC class I or class II proteins on the surfaces of other cells, including professional antigen-presenting cells and potential target cells.

B-cell receptor
: An immunoglobulin molecule that is displayed on the surface of a B cell that enables this cell to recognize and respond to specific antigens.

antibody
: A soluble tetrameric protein that is produced by plasma cells of the immune system and is capable of recognizing and binding particular antigens with high specificity. *See also* **immunoglobulin**.

variable region
: Portion of an antibody molecule or T-cell receptor that contains the antigen-binding domain and, within an individual organism, is present in millions of alternative versions (and thus alternative amino acid sequences) in the various antibody molecules that together comprise a given class of antibody molecules such as gamma immunoglobulin. *Compare* **constant region**.

constant region
: Portion of an antibody molecule that is present identically by all members of a class of these molecules, e.g., all immunoglobulin gamma molecules. *Compare* **variable region**.

heavy chain

Larger of the two polypeptide chains that assemble to form immunoglobulins and related proteins. *Compare* **light chain**.

light chain

Smaller of the two polypeptide chains that assemble to form immunoglobulins and related proteins. *Compare* **heavy chain**.

immunogen

(adj., - **genic**) A chemical structure that is capable of provoking some type of immune response, e.g., an antigen that can provoke the synthesis of antibody molecules capable of recognizing and binding it.

T lymphocyte

Class of lymphocytes that develops largely in the thymus and includes T_H cells, T_C cells, and T_{reg}'s.

B cells

Lymphocytes, also termed B lymphocytes, that develop in the bone marrow and are involved in generating the humoral immune response. *See also* **T cells**.

innate immune response

An immune system response toward an antigen or a cell that occurs in the absence of prior exposure of an organism to this particular antigen or cell. *See also* **adaptive immune response**.

adaptive immune response

An immune system response that is acquired or learned following exposure of an organism to an antigen or antigen-bearing agent. *See also* **innate immune response**.

OceanofPDF.com

15.4 The diversity of B cell and T cell receptors arises from the stochastic diversification of the genes that encode them

During the generation of T lymphocytes and B lymphocytes, a highly unusual process of immunoglobulin diversification (including diversification of soluble antibodies as well as the membrane-tethered TCRs and BCRs) is achieved by the intensive diversification of the genomic nucleotide sequences that encode the V regions of these various proteins. Unlike essentially all other genes in the human genome, the genetic sequences encoding antibodies and thus B-cell receptors are not inherited in the germ line and therefore are not present in the lymphocyte progenitor cells at birth. Instead, a few hundred distinct subgenic segments that are indeed inherited in the genome can combine with one another almost randomly in any one of thousands of different ways as the immune system matures (**Supplementary Sidebar 15.1**). A similar process of rearrangement and assembly of subgenic segments of T-cell receptor genes generates a diverse repertoire of T-cell receptors. The resulting combinatorially assembled, fused subgenic sequences underlie the staggering diversity of T- and B-cell populations; the potential diversity of T-cell and the B-cell repertoires of an individual human each exceed 10^9 potential antigen specificities. In aggregate, these specificities enable T and B cells to recognize and bind almost any antigen that might be encountered during a lifetime. (Actually, only a tiny subset of these possible antigens is ever encountered by an individual human.)

In fact, the organization of the process of random gene rearrangement ensures that only one of the very large number of possible gene rearrangements is allowed to assemble within a given lymphocyte precursor. Once a new antigen-combining site has been assembled in a

lymphocyte precursor (through the process of stochastic combinatorial fusion of encoding DNA segments described above), subsequent recombination events are blocked in that cell and its descendants. Therefore, a lymphocyte precursor cell and its lineal descendants carry genes that encode the ability to recognize only one specific cognate antigen (or set of structurally similar antigens). Accordingly, all antigen receptors or all of the antibody molecules made by a given lymphocyte are identical to one another at the molecular level and all exhibit identical antigen-recognizing specificity.

Importantly, the chance diversification of these antigen receptor genes occurs in the absence of any direct provocation by encounters with specific antigens. Instead, diversification simply allows the immune system to anticipate future challenges arising from an essentially unlimited number of antigens, each composed of a molecular structure that might not have been encountered previously by an individual but might well be encountered during the individual's lifetime. Among these novel antigens are some that have never been encountered during the evolutionary history of the animal species to which the individual belongs.

An encounter with an antigen can provoke the proliferation of a lymphocyte whose antigen receptors (antibody molecules, BCRs, or TCRs) recognize the antigen's detailed molecular conformation. As a consequence, repeated cycles of cell division of an antigen-provoked lymphocyte and its direct descendants produce a large clonal population of cells that all share the same antigen-binding specificity as the parental lymphocyte in which an initial immunoglobulin or T-cell receptor gene rearrangement took place. The proliferation of a clone of B or T lymphocytes in response to an encounter with a specific antigen is referred to as clonal expansion. In effect, the antigen that provokes this clonal expansion functions much like a mitogenic growth factor impinging on non-immune cells throughout the body (see Chapter 5). Antigen-provoked clonal expansions are formally similar to the clonal expansions that occur during multi-step tumor progression (see Figure 11.14) as a consequence of the acquisition of advantageous, somatically generated, mutant alleles. The clonal expansions of lymphocytes generate the large populations of these cells that can

mediate actual responses to a newly encountered antigen, replacing the initially small number of cells that were incapable of doing so.

An inherent hazard of the system that allows the stochastic generation of antibodies and T-cell receptors is the likelihood that such a process will generate receptors that exhibit a specificity for antigens expressed by the body's own normal cells, that is, "self." The formation of such antigen receptors may open the door to an attack within a host organism by its own immune system, resulting in an autoimmune disease. Such an attack is said to be launched by autoreactive lymphocytes and antibody molecules.

In fact, most lymphocytes that happen to have developed strong reactivity to the antigens expressed in normal tissues are eliminated soon after their development; this elimination occurs in the tissues termed primary lymphoid organs where they were generated, these being either the thymus in the case of T cells or the bone marrow in the case of B cells. Deletion of autoreactive cells must operate efficiently lest life-threatening autoimmune diseases occur. Moreover, it is this deletion that lies at the heart of immunological tolerance (**Sidebar 15.1**).

Sidebar 15.1 Inappropriate gene expression may yield protein antigens that escape immune tolerance

The development of immune tolerance depends on the ability of the immune system to recognize self-antigens and eliminate the lymphocytes that happen to have developed reactivity with these antigens. This process is highly effective but never flawless. As an example, deviations from normal patterns of antigen synthesis and presentation may be undertaken by cancer cells, which may well derive, in turn, from aberrant patterns of gene expression in these cells; such shifts in the transcriptomes of cancer cells may yield, among other aberrations, the inappropriate expression of proteins normally restricted to earlier stages of development and thus no longer expressed in adult tissues. Such aberrantly expressed antigens may not have provoked the development of immune tolerance toward them.

Alternatively, cancer cells may develop ectopic expression of proteins whose synthesis is normally restricted to special sites in the body, such as

the testes; such proteins may not have previously elicited the development of immune tolerance, simply because they are expressed in anatomical sites that are usually inaccessible to the components of the adaptive immune system that are responsible for the development of tolerance. These various types of antigens that have failed (for one reason or another) to induce tolerance and are displayed by tumor cells represent excellent candidates for recognition and attack by components of the adaptive immune system.

OceanofPDF.com

Glossary

clonal expansion
: Process by which a cell that has acquired a more advantageous phenotype generates a large population of lineal descendant cells, which in aggregate constitute a clone; such clonal populations may be generated during the process of tumor progression or in lymphocytes that are stimulated to proliferate by encounter with an antigen that is cognate with the cell surface receptor that they display.

autoimmune
: Referring to a process or disease in which the immune system attacks an organism's own normal cells and tissues. *See also* **autoreactive**.

autoreactive
: Referring to the ability of components of the adaptive immune system —including antibody molecules and lymphocytes—to recognize and react with antigens displayed by normal tissues, resulting in autoimmunity. *See also* **autoimmune**.

OceanofPDF.com

15.5 MHC molecules play key roles in antigen recognition by T cells

Only those members of the huge, diversified lymphocyte population encountering an antigen that happens to bind their antigen receptor (that is, a BCR or TCR) will be activated to divide and differentiate into cells that perform the effector functions (the actual work) of their lymphocyte type. Antibody production is the primary effector function of B cells, whereas the effector functions of T cells are more variable, depending on which of the broad categories of helper, regulatory, or cytotoxic T-cell functions they are destined to perform; these subcategories of T cells are usually denoted as T_H, T_{reg}, and T_C cells, respectively.

An understanding of the molecular mechanisms through which T cells are cued to play their assigned roles in controlling cancer begins with an appreciation of precisely how T cells recognize antigens, specifically antigens expressed by other cells, such as cancer cells, including those proteins that reside within these other cells. This recognition is complicated by the fact that cells of the immune system do not have the capacity to peer inside other cells including cancer cells. Instead, in order to circumvent this problem, the contents of cells must be displayed on the surface of such cells, allowing them to be sensed by the immune system. The ability to surveil the internal contents of cells is critical given the fact that the majority of cancer-associated antigens are intracellular proteins rather than proteins that are naturally displayed on the surface of cancer cells.

This prerequisite for effective immune surveillance provides the rationale for the cellular machinery that has evolved specifically to display samples of the intracellular contents on the cell surface. In the case of protein-associated antigens—essentially all of the antigens discussed here—this surveillance depends, more specifically, on fragments of such proteins being presented at the surface. These fragments are generated by ongoing proteolysis in the cytoplasm of a portion of recently synthesized proteins.

Major histocompatibility complex (MHC) molecules are responsible for displaying fragments of intracellular proteins on the surfaces of all the body’s cells. These molecules are tasked with the function of acquiring peptide

fragments of recently synthesized proteins and conveying them to the cell surface, where they are subsequently displayed and may, in principle, be recognized by TCRs.

MHCs are transmembrane proteins that are topologically much like the growth factor receptors and integrins described in Chapter 5. However, the functions of these classes of cell surface molecules are totally different: growth factor receptors transduce signals into cells informing the intracellular circuitry of conditions in the outside world, in particular the extracellular space immediately surrounding a cell. In stark contrast, MHC molecules function in precisely the opposite fashion by conveying signals (in the form of peptide:MHC complexes) to the cell surface, where they are displayed to the outside world, more specifically to components of the immune system.

The cells of an individual mammal can muster a diverse array of MHC molecules. These molecules are encoded by highly polymorphic alleles in the genome. (Recall that a genetic polymorphism is a variant allele whose protein products support normal cellular and organismic function.) The polymorphic variants of MHC molecules carry functional pockets that are capable of binding many of the diverse peptides generated by intracellular proteolysis and thereafter conveying the bound peptides to the cell surface for display to the outside world (**Sidebar 15.2**).

Sidebar 15.2 MHC polymorphism has functional consequences

The MHC complex is a closely linked cluster of genes that is present in the genome of all vertebrate species. Together with bound peptides, proteins encoded by the MHC form the antigenic structures recognized by T cells. In humans, MHC molecules are termed instead HLA molecules. There are two classes of MHC molecules, MHC class I (MHC-I) and MHC class II (MHC-II). MHC molecules all have a functional pocket, a molecular cleft that binds some peptides but not others in order to form the peptide:MHC complexes that TCRs recognize. MHC molecules are encoded, as mentioned, by highly polymorphic genetic loci, each of which hosts multiple alternative alleles. By now, more than 10,000 distinct MHC alleles have been catalogued in the human gene pool. This diversity is a direct reflection of the need to maximize the chances that an MHC molecule of one variant subtype or another will contain a molecular cleft that selectively binds some members of the diverse population of peptides generated by post-translational intracellular proteolysis of recently synthesized proteins.

Bear in mind that although peptide binding by MHC molecules is somewhat selective, it is highly promiscuous, and any particular MHC molecule is capable of binding a large number of different peptides. This means that in an outbred vertebrate population, such as humans, it is virtually impossible for a pathogen to evolve proteins that will not, upon proteolysis, generate peptides that can be bound by at least some MHC class I and class II molecules displayed by certain individual members of a mammalian species. This combination of MHC polymorphism and peptide-binding promiscuity would seem to guarantee that the species as a whole cannot be driven to extinction by exposure to one or another novel infectious agent. This versatility of peptide binding extends as well to those generated from the proteins expressed by cancer cells: even in a single individual, it is likely that at least some peptides generated from novel antigens arising in cancer cells have a probability of being bound by at least one of the class I or class II MHC molecules encoded in this individual's genome.

Given the large number of polymorphic alleles and the number of loci that carry these alleles, each individual member of a species is likely to carry a combination of MHC molecules that differs significantly from the combination of MHC molecules expressed by almost everyone else. The most obvious exceptions to this are identical twins in humans and members of specific inbred strains of mice in which all individual mice are genetically identical to one another. This polymorphic variability has another immunological consequence: every individual's cells will express at the surface a combination of MHC molecules that is unique (or almost so). Although the assigned task of MHC molecules is to *present* intracellular peptides, enabling the latter to be recognized as antigens, these MHC molecules themselves, independent of their peptide-displaying powers, become antigens in their own right that are readily recognized by components of the immune system. Within an individual's body, these MHC molecules are, quite naturally, the object of immunological tolerance; however, when this individual's cells or tissues are transplanted into the body of a genetically nonidentical person, they will almost inevitably be recognized as foreign because these donor cells and tissues express MHC molecules that the recipient's immune system has not previously experienced.

These dynamics explain historically the origin of the term *major histocompatibility complex,* which derived from the observation that tissues and cells of some organisms can be readily transplanted into other syngeneic organisms; the transplanted donor tissues are therefore "histo" (meaning "tissue") compatible with the recipient hosts. Conversely, transplanted donor tissue that is nonsyngeneic with a potential graft recipient was seen to be rejected by the

recipient and was therefore deemed to be *histoincompatible*. (Indeed, the MHC genetic complexes were discovered because of the strong immunogenicity of their encoded proteins, which were found to be major sources of graft recognition and rejection.)

Given the high degree of polymorphism in MHC molecules, differences in MHC repertoires among members of an outbred species, such as our own, are assured. Consequently, transplantation of cells, tissues, or organs between members of a population that are not genetically identical are likely to fail unless powerful immunosuppressive measures are taken to prevent anti-graft rejection responses in tissues of the recipients.

Importantly, the polymorphic variability of MHC molecules is not generated by rearrangements of DNA segments inherited through the germ line, as described earlier (see **Supplementary Sidebar 15.1**), but preexists in the encoding germ-line sequences inherited from parents. Moreover, this diversity of MHC molecules displayed by a given vertebrate cell exists in order to enable a subset of them to bind, with some degree of affinity, a portion of the peptides that are generated by proteolysis of that cell's intracellular contents. In all vertebrates, the loci of genes encoding the two major types of MHC molecules—class I and class II—as well as several other genes encoding many of the proteins essential for antigen presentation, are closely linked to one another in a region of the genome referred to as the MHC complex.

As cited above and described in detail later in this chapter, the recognition of cancer cells by components of the immune system depends on the ability of immune effector cells to recognize MHC-bound peptides displayed on the surfaces of the neoplastic cells. As indicated earlier, these peptides are produced continuously in cells and, in principle, are created by the systematic cleavage of a portion of all the proteins that are synthesized inside a cell; accordingly, they include proteins made by normal cells, proteins made by cancer cells, and proteins made by pathogen-infected cells. One immediate and direct implication is that the failure of a cancer cell to display cancer-associated peptides borne by its MHC molecules may enable that cancer cell to evade detection and subsequent attack by T cells of the immune system.

There are two types of cell surface MHC molecules, MHC class I (class I or MHC-I) and MHC class II (class II or MHC-II), and there is a marked difference in the patterns of their expression among the diverse cell types in the body.

Essentially all nucleated cells display class I MHC molecules, revealing how far-reaching is the ability of the immune system to monitor intracellular proteins—including those made by infectious agents within infected cells—throughout the body. Class II expression, however, is mostly restricted to only a few types of cells with specialized immune-related functions, specifically dendritic cells, B cells, and macrophages, as well as others we need not consider here. As will become apparent, these differences have important functional consequences. The restricted expression of the class II MHC molecules and the specialized function of these class II molecules have caused this small number of immune cell types to be called antigen-presenting cells (APCs).

Both MHC-I and MHC-II molecules carry the clefts cited earlier that serve as selective binding sites for the peptides generated by intracellular proteolytic degradation. In effect, these peptide-binding clefts serve as the palms of the hands of these MHC molecules that grab peptides inside the cell and display them outside the cell at its surface. The resulting complex of a peptide and MHC molecule forms a three-dimensional structure that is unique for any particular combination of peptide and MHC and is the structural feature on the surface of a cancer cell that may be recognized by a T-cell receptor (see Figure 15.7).

The relatively small size of the peptide-presenting cleft together with the size of captured peptides, typically 8 to 10 amino acid residues for MHC-I and 13 to 20 or so for MHC-II, create a problem: the interaction domains between the peptide and the MHC cleft that hosts it depend, by necessity, on a small number of noncovalent interactions between the two. Indeed, complex bioinformatic algorithms have been developed to predict whether a given peptide generated by proteolytic cleavage within a cell will find a firm roost in one of a cell's repertoire of MHC molecules and thus have a chance of being carried to a cell surface and displayed there.

These facts suggest that when both a wild-type and corresponding mutant peptide are properly displayed on the cell surface, a subtle structural difference between them may suffice to provoke an immune recognition of the difference between them. Thus, during the development of the immune system, the wild-type peptide should have elicited tolerance and should thereby be overlooked by the multiple arms of the adaptive immune system; in contrast, a single amino acid-substituted peptide version of the wild-type peptide may stand out and be highly successful in attracting the attention of the immunocytes that form the adaptive arm of this system. This explains how a cell bearing a single cancer-associated mutant allele

can generate peptide:MHC complexes that have the potential to be recognized by T cells, the agents of adaptive immunity responsible for such recognition.

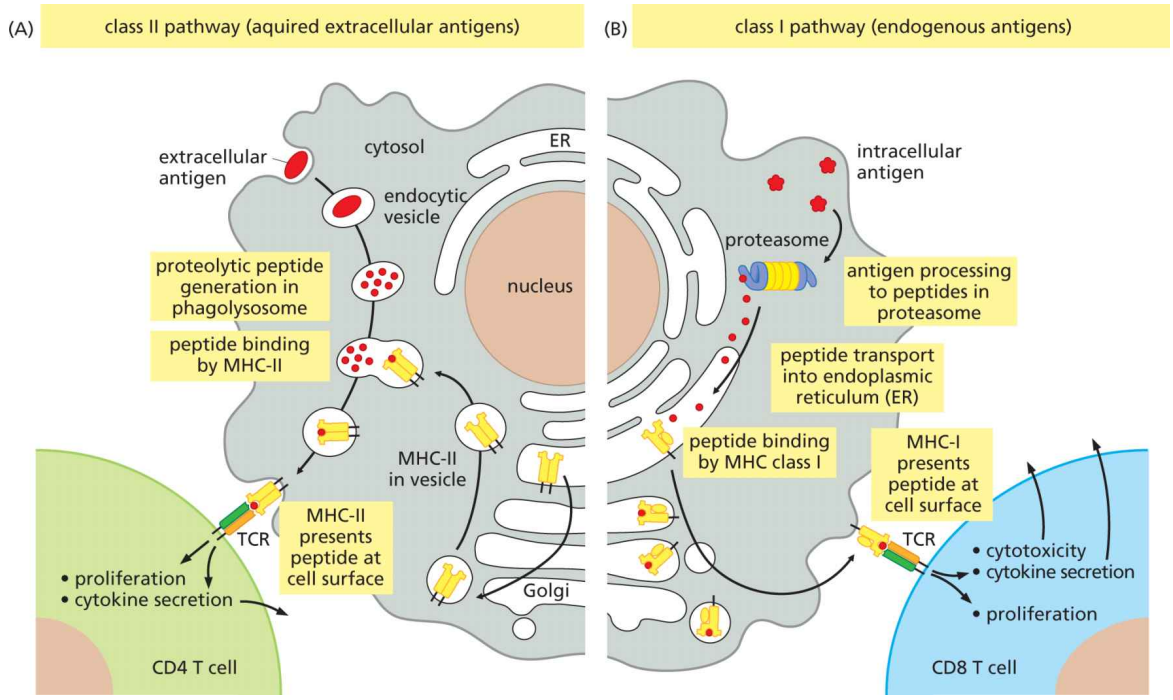
Importantly, the peptides presented by the two classes of MHC molecules have different origins. MHC-I selectively binds peptides generated from proteins initially synthesized within the *same cell* that later displays this peptide:MHC complex on its surface. Given the almost universal expression of MHC class I molecules throughout all cell types in the body, this implies that a portion of each protein made by a cell anywhere in the body is diverted from its dedicated function and destination site and is, instead, subjected to intracellular proteolysis and subsequent cell surface display via MHC-I molecules.

The MHC-II molecules displayed by a cell operate very differently: they selectively bind peptides derived from proteins initially synthesized in *other cells* in the body that were previously acquired by antigen-presenting cells (APCs), internalized into these cells (by phagocytosis, endocytosis, or pinocytosis), subsequently degraded into peptides, and only then loaded onto an MHC-II molecule and presented at the cell surface. The ability to perform this function, involving antigen acquisition and subsequent cell surface presentation, is not ubiquitous; rather this function is restricted to the APCs enumerated earlier, specifically B cells, macrophages, and most importantly, dendritic cells (DCs).

These unique capacities enable itinerant, “professional” antigen-presenting cells to survey the contents of cells and fluids throughout the body, including infecting microbes and cancer cells, ingest them, digest them, and ultimately present resulting peptides to other components of the immune system, making possible the subsequent development of an effective immune response. To be more specific, this MHC-II–mediated presentation by APCs of acquired peptides is made to T cells, which respond in various ways to create various aspects of the immune response.

Dendritic cells represent the most potent class of APCs, because they possess, by far, the greatest capacity to present certain peptides generated from proteins synthesized in other cells. In addition, because DCs share traits with essentially all other cells in the body, they can also present oligopeptides on their surface via their MHC-I molecules. Hence, DCs employ both MHC-I and MHC-II to display peptides at their surface. In both cases, T cells represent the audience that views and responds to these two types of antigen presentation. The T cells, in turn, proceed to operate as the key organizers, amplifiers, and in many cases, the effectors of adaptive immune responses to microbes and cancer. The pathways

leading to presentation of peptides on class I or class II MHC molecules are presented schematically in **Figure 15.8**.



A two-part figure depicting two different pathways of antigen processing. Part A depicts a class 2 pathway (acquired extracellular antigens). An extracellular antigen entering a cell's cytosol is enclosed in an endocytic vesicle. Proteolytic peptide generation in a phagolysosome is followed by peptide binding by an M H C-2, which moved from a Golgi body to a vesicle to the binding site. When the M H C-2 presents the peptide at the cell surface, the T cell receptor of a C D4 T cell binds to it, resulting in proliferation of the T cell and secretion of cytokines. Part B depicts a class 1 pathway (endogenous antigens). This pathway begins with intracellular antigens. Antigen processing to peptides takes place in a proteasome. The peptides are then transported into the endoplasmic reticulum, where they are bound by M H C class 1. When the M H C-1 presents the peptide at the cell surface, the T cell receptor of a C D8 T cell binds to it, resulting in proliferation of the T cell, cytotoxicity, and secretion of cytokines.

Figure 15.8 Different pathways of antigen processing present antigen-derived peptides to CD4 and CD8 T cells (A) Class II pathway: presentation to CD4 T cells. Extracellular antigens—notably those produced by other cells (*red oval*, *upper left*) and then internalized by phagocytic cells, especially dendritic cells (via phagocytosis, endocytosis, or pinocytosis)—

soon become enclosed in endocytic vesicles, some of which fuse with phagolysosomes in the cytoplasm, where their contents are subjected to proteolysis, resulting in the generation of peptides (*red dots*), some of which are then bound by MHC-II. The resulting peptide:MHC-II complexes are exported to the cell surface by vesicular transport and presented to T-cell receptor (TCR) displayed by an adjacent $CD4^+$ T cell (*light green*, *lower left*). Recognition of these cell-surface peptide:MHC-II complexes by the TCR of a $CD4^+$ T cell can induce its proliferation and its secretion of certain cytokines. (B) Class I pathway: presentation to CD8 T cells. A portion of the recently synthesized proteins within a cell routinely undergo proteasome-mediated proteolysis, generating peptides that are transported into the endoplasmic reticulum (ER), where some are bound within the lumen of the ER by newly synthesized MHC-I molecules. Subsequent transport first to the Golgi apparatus and then to the cell surface results in the presentation of the peptide:MHC-I complexes at the cell surface. Recognition of peptide:MHC-I complexes by the TCRs of nearby CD8 cells (*light blue*, *lower right*) can induce these cells to undergo proliferation, secrete cytokines, and differentiate into cytotoxic T lymphocytes (CTLs, *not shown*) that can kill cells bearing peptide–MHC complexes recognized by their TCRs. (Adapted from P. Parham, The Immune System, 5th ed. New York: W.W. Norton & Company, 2021, Figure 5.17.)

OceanofPDF.com

Glossary

effector
: An agent (such as a protein) that carries out the actual work of a biological process rather than simply regulating it.

MHC class I
: A class of cell surface proteins that is specialized to acquire (during its maturation within the endoplasmic reticulum) oligopeptide fragments of its own intracellular proteins and thereafter present these fragments on the cell surface where they may be recognized by components of the adaptive immune system such as CD8+ lymphocytes. *Compare* **MHC class II**.

MHC class II
: A class of cell surface proteins that is specialized to acquire (during its maturation within the endoplasmic reticulum) oligopeptide fragments of acquired phagocytosed cells or particles and thereafter present these fragments on the cell surface where they may be recognized by components of the adaptive immune system such as CD4+ lymphocytes. *Compare* **MHC class I**.

antigen-presenting cells
: A class of cells—often termed professional antigen-presenting cells, including dendritic cells, macrophages, and B cells—that present oligopeptide antigens via class I and II MHC molecules to other immunocytes, notably helper and cytotoxic T cells.

phagocytosis
: Endocytotic process by which a cell, usually a component of the immune system, engulfs a particle (which may be another cell), internalizes this particle, and usually proceeds to degrade it by introducing it into lysosomes. *See also* **endocytosis**.

endocytosis
: Uptake by a cell of extracellular material together with associated extracellular fluid that is achieved through the invagination of a patch of plasma membrane, thereby yielding membrane-bound vesicles termed endosomes within the cytoplasm. Pinocytosis and phagocytosis are forms of endocytosis. *See also* **exocytosis**, **endosome**, **phagocytosis**, **pinocytosis**.

pinocytosis

Process similar to endocytosis in which a small volume of extracellular fluid together with its dissolved contents is internalized by the invagination of patches of plasma membrane, yielding cytoplasmic vesicles. *See also* **endocytosis**.

15.6 T cells that recognize MHC-I have different roles from those that recognize MHC-II

The T cells that respond to antigen presentation via either MHC-I or MHC-II fall into two distinct subtypes. In both cases, the responses depend on TCRs displayed by the T cells. Whether a TCR recognizes MHC-I–bound or MHC-II–bound peptides is determined by a co-receptor protein that is associated closely but noncovalently with this TCR on the cell surface adjacent to this TCR. The co-receptors do not have any antigen-recognizing function of their own, but instead ensure that the TCR with which they are partnered is directed toward the appropriate type of MHC molecule, that is, toward either MHC-I or MHC-II. More specifically, CD4 and CD8 molecules, functioning as co-receptors, direct their TCR partners to bind either MHC-II complexes (CD4) or MHC-I complexes (CD8) displayed by other cells. Indeed, the two dominant classes of T lymphocytes are named $CD4^+$ or $CD8^+$ T cells after their co-receptors (or, more simply, CD4 T cells and CD8 T cells). Thus, a given T lymphocyte will display either a CD4 or CD8 co-receptor and belong to either the $CD4^+$ or $CD8^+$ class of T cells.

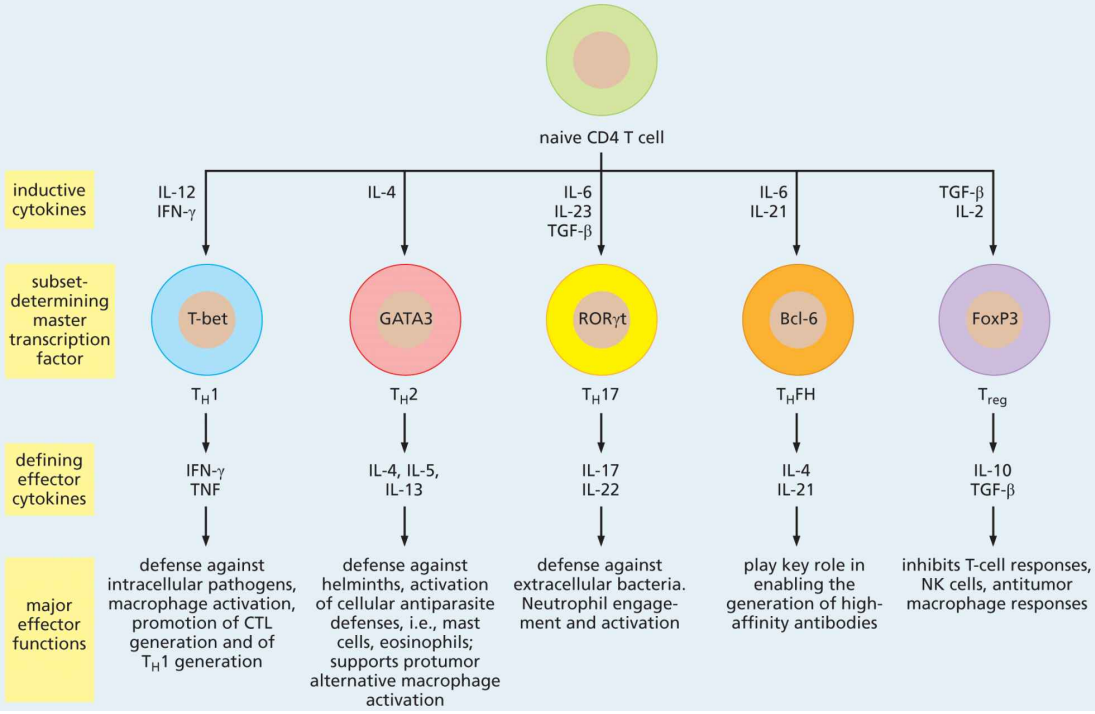
Having interacted with appropriate MHC molecules, these two classes of T cells undertake very different specialized functions. The CD8 T cells, which are specialized to interact with MHC class I molecules, depend on this interaction to recognize cells that are to be targeted for killing; this explains why CD8 T cells are often termed cytotoxic T cells (T_C) or cytotoxic T lymphocytes (CTLs). It is these CD8 T cells that carry out the hard work of recognizing and eliminating cancer cells bearing certain peptide:MHC-I complexes on their surface (see Figure 15.8). Conversely, CD4 cells are specialized to recognize the peptide:MHC-II complexes displayed by APCs and, having done so, provide signals that help to activate, support, and coordinate the behavior of several other types of T cells—including, most importantly, CD8-bearing cytotoxic T cells. For this reason, CD4 lymphocytes are often termed helper T cells (T_H cells).

The existence of T_H cells reveals a new mode of immunocyte function, in that these cells act primarily to regulate and stimulate other lymphocytes. Stated differently, the actions of other immunocytes often depend on previous stimulation or support by T_H cells. Within the class of CD4 T cells there are multiple subsets, each assuming a different set of functional responsibilities (**Sidebar 15.3**).

Sidebar 15.3 CD4 +T-cells belong to multiple subtypes

T lymphocytes of the CD4 category are responsible for a broad range of activities that stimulate, coordinate, or otherwise regulate the responses of multiple types of immune cells. This is accomplished at the time of their activation by the differentiation of naive T cells into one of five major effector $CD4^+$ T-cell subsets. Each of these effector subsets orchestrates a distinct function or set of functions. The specific path of differentiation into each of these subsets is determined by the cytokines present during the initial antigen-triggered activation of the naive CD4 cell and involves the expression of a key transcription factor that determines subset identity.

Each T-cell subset is distinguished by the secretion of its own distinct set of cytokines, each providing the means to direct the behavior of specific target cell populations under its control, that is, the particular cell populations that are being helped by the specialized CD4 T-cell subset. **Figure 15.9** provides a summary profile of five widely recognized T-cell subsets. Four of the five CD4 T-cell subsets play a role in activating or intensifying the responses of the immunocytes they target, thereby supporting or augmenting their functional capabilities. In sharp contrast, the fifth subset is composed of regulatory T cells, T_{reg}'s, which *suppress* the activities of the immune cells that they target.



Five T-cell subsets derived from naive C D 4 T cells. T H 1 cells are induced by interleukin 12 and interferon gamma. The master transcription factor is T-bet. The

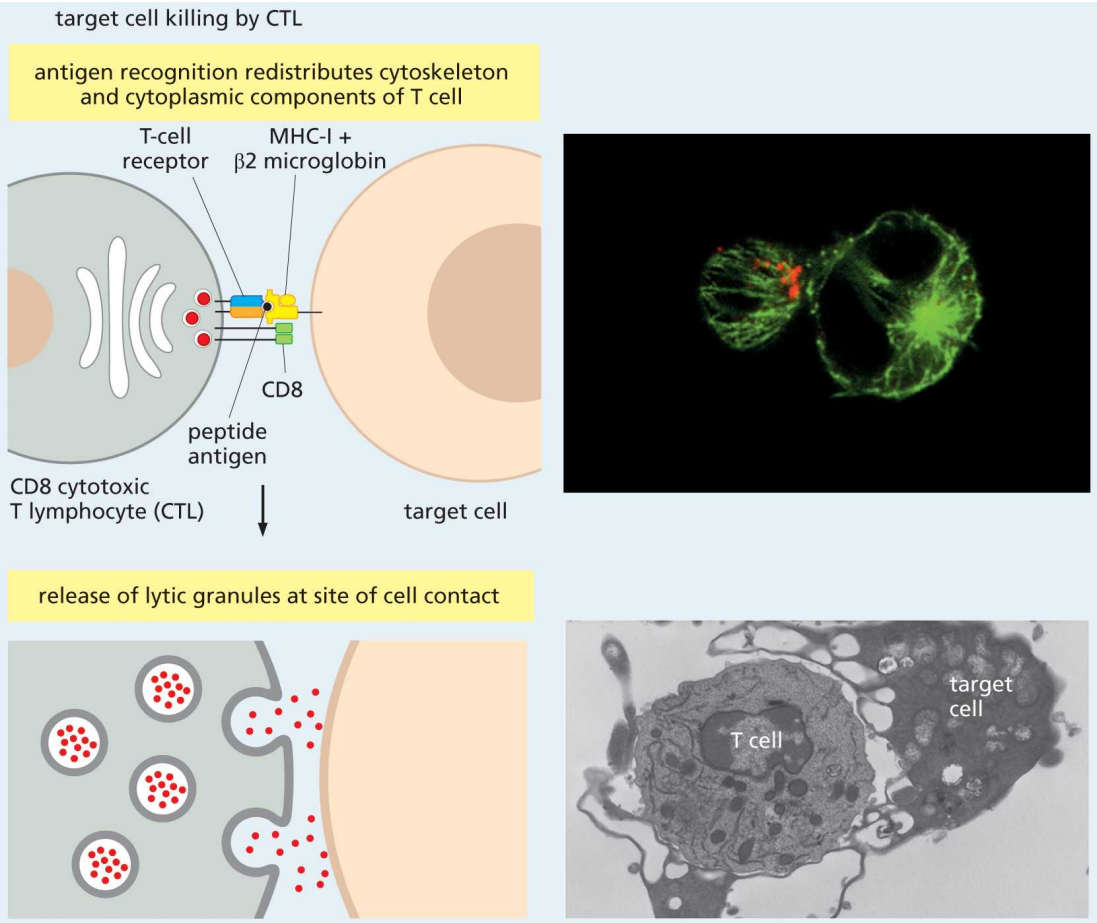
defining effector cytokines are interferon gamma and Tumor necrosis factor. The major effector functions are defense against intracellular pathogens, macrophage activation, and promotion of C T L generation and of T H 1 generation. T H 2 cells are induced by interleukin 4. The master transcription factor is GATA 3. The defining effector cytokines are interleukins 4, 5 and 13. The major effector functions are defense against helminths, activation of cellular antiparasite defenses, i.e., mast cells, eosinophils; and support of protumor alternative macrophage activation. T H 17 cells are induced by interleukins 6 and 23 and by transforming growth factor beta. The master transcription factor is R O R gamma t. The defining effector cytokines are interleukins 17 and 22. The major effector functions are defense against extracellular bacteria, and Neutrophil engagement and activation. T H F H cells are induced by interleukins 6 and 21. The master transcription factor is B c l-6. The defining effector cytokines are interleukins 4 and 21. These cells play a key role in enabling the generation of high affinity antibodies. Regulatory T cells are induced by transforming growth factor beta and interleukin 2. The master transcription factor is Fox P3. The defining effector cytokines are interleukin 10 and transforming growth factor beta. The major effector functions are to inhibit T-cell responses, NK cells, and antitumor macrophage responses.

Figure 15.9 T-cell subsets Five of the most studied of the known T-cell subsets derived from naive T cells (*above*) are shown, and the cytokine or cytokines essential for their induced differentiation are identified. As indicated, the expression of a key and distinctive transcription factor or factors is required for differentiation into each subset. Once formed, each subset secretes a characteristic profile of effector cytokines that promotes the indicated effector functions (*bottom*). (Adapted from P. Parham, The Immune System, 5th ed., New York: W.W. Norton & Company, 2021.)

At first glance, it might seem that the CD8-bearing cytotoxic T lymphocytes (CTLs) are limited to attacking and eliminating cells from our tissues that are somehow aberrant and worthy of recognition and elimination, often because they express aberrant cellular proteins and give rise to peptides that provoke attack when displayed as peptide:MHC-I complexes on their surface. Cancer cells feature prominently in the list of such aberrant cells. CTLs are also an important arm of the *antiviral* immune defenses of the body because they can recognize virus-infected cells displaying virus-derived peptide:MHC complexes and attack these cells, eliminating them. In so doing, the CTLs destroy the factories in which replicating viruses generate progeny virus particles. In a larger sense, CD8 T cells are a key line of defense against a variety of intracellular pathogens that depend on their cellular hosts to multiply (**Sidebar 15.4**).

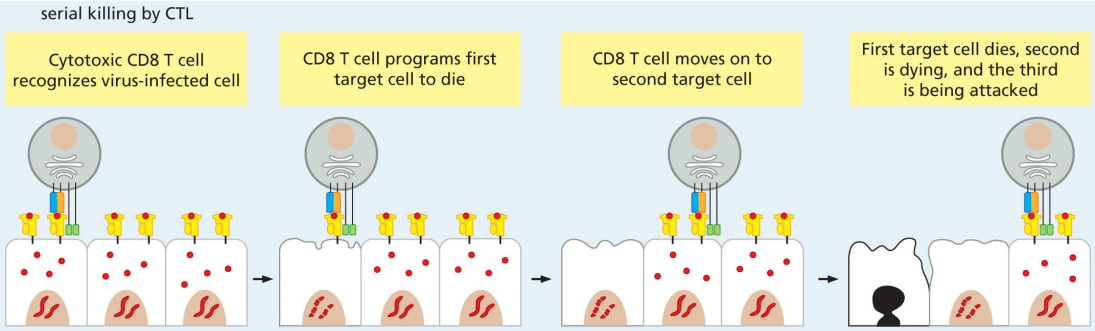
Sidebar 15.4 CTLs use well-defined mechanisms to kill their targets

A cell's display of certain peptide antigens on its surface (via its MHC class I molecules; see Figure 15.7) may subsequently attract the attention of certain cytotoxic T lymphocytes (CTLs or T_C), which migrate out of the lymph nodes following their activation by APCs, enter into the circulation, and thereafter enter into various peripheral tissues to search for appropriate targets. When a CTL encounters a cell displaying the specific peptide:MHC complex recognized by its TCR, it will launch an attack on this cell with the goal of killing it. In fact, cytotoxic T cells deploy two distinct mechanisms to kill their targets, relying either on granule exocytosis (**Figure 15.10A**) or on death-inducing ligands (see Figures 9.31 and 9.32). Thus, CTLs can attack their intended victims through the secretion of granules containing toxic proteins, such as perforin and granzymes. Perforin, for its part, punches holes in the plasma membranes of targeted cells, allowing granzymes to enter the target's cytosol, where they can activate the intrinsic apoptotic pathway shown in Figures 9.31 and 9.32. The alternative killing mechanism involves the Fas death receptor, which is displayed on some cell types. CTLs can present FasL, the ligand of the Fas receptor, to their target cells, activating the Fas death receptors on the surfaces of the targeted cells and triggering the extrinsic apoptotic pathway within these cells (see Section 9.14).



Target cell killing by a cytotoxic T lymphocyte, with two diagrams and two micrographs. In the first diagram, antigen recognition redistributes cytoskeleton and cytoplasmic components of a T cell. The T-cell receptor on a C D8 cytotoxic T lymphocyte is shown binding to a peptide M H C complex on a target cell. Beside the diagram is a fluorescence microscopy image of a cytotoxic T lymphocyte attacking a larger target cell. The microtubular networks of both cells appear in green. The lymphocyte has bright red dots concentrated near the point of contact with the target cell. These events lead tc the second diagram, showing release by the T cell of lytic granules at the site of cell contact. A micrograph shows the effect on the target cell: it is dissolving where it is in contact with the T cell.

(A)



A diagram, in four panels, of serial killing by a cytotoxic T lymphocyte. A Cytotoxic C D8 T cell is shown recognizing a virus-infected cell. The C D8 T cell programs the first target cell to die. Then the C D8 T cell moves on to the second target cell. In the last panel, the First target cell dies, the second is dying, and the third is being attacked.

(B)

Figure 15.10 Killing of target cells by cytotoxic CD8-expressing T cells (CTLs) (A) Recognition of peptide:MHC-I complexes on the surface of target cells by the T-cell receptor together with the associated CD8 co-receptor of a CTL (*diagram*) causes a reorganization of cytoplasmic elements within the CTL (*micrograph*). As seen in the micrograph, the engagement prompts alignment of the CTL's Golgi apparatus and granules containing cytotoxins, such as granzymes, toward the target cell. The micrograph shows the microtubular networks of both cells (*green fluorescence*) and the lytic granules of the attacking CTL (*red fluorescence*). Subsequent fusion of these lytic cytotoxin-containing granules with the plasma membrane of the CTL results in the release and deposition of their cargo directly onto the membrane of the closely apposed target cell (*middle left*). The accompanying electron micrograph (*middle right*) shows the breakdown of

intracellular elements suffered by a target cell sometime after being exposed to a granule-mediated attack by a T cell. (B) Serial killing by a CTL. A cytotoxic CD8 T cell can recognize peptide:MHC-I on one cell, program it for apoptotic death by delivering lytic granules, release it, and serially repeat the process of cell recognition, programming for death, and release. The course of the apoptosis program is illustrated by the changing configuration of the cells (*bottom*, *left to right*). This capacity allows a single CTL to kill other cells in the vicinity that bear peptide:MHC-I complexes recognized by its TCR. (A, Gillian Griffiths. B, Republished with permission of Springer, Kluwer/Plenum, Mechanisms of Cell-Mediated Cytotoxicity II, Second International Workshop on Mechanisms in Cell-Mediated Cytotoxicity. Annapolis, Maryland, June 10-13, 1984.)

Such CTL-mediated attacks on target antigen-displaying cells (see Figure 15.10A) represent a major component of the cellular arm of the adaptive immune response and play an important role in the elimination of aberrant cells, notably virus-infected cells and cancer cells. Finally, we should note that CTL-mediated killing is efficient; a single CTL may serially engage and kill one target cell after another (Figure 15.10B).

OceanofPDF.com

Glossary

co-receptor
: Cell surface protein that is displayed in conjunction with a nearby receptor and modulates the function of the latter by modulating its ligand specificity or signaling powers.

helper T cell
: A subtype of T cell that is identified by its expression of the CD4 co-receptor and functions to stimulate and amplify the functions of B cells and effector T cells, most importantly the CD8+ cytotoxic T cells.

OceanofPDF.com

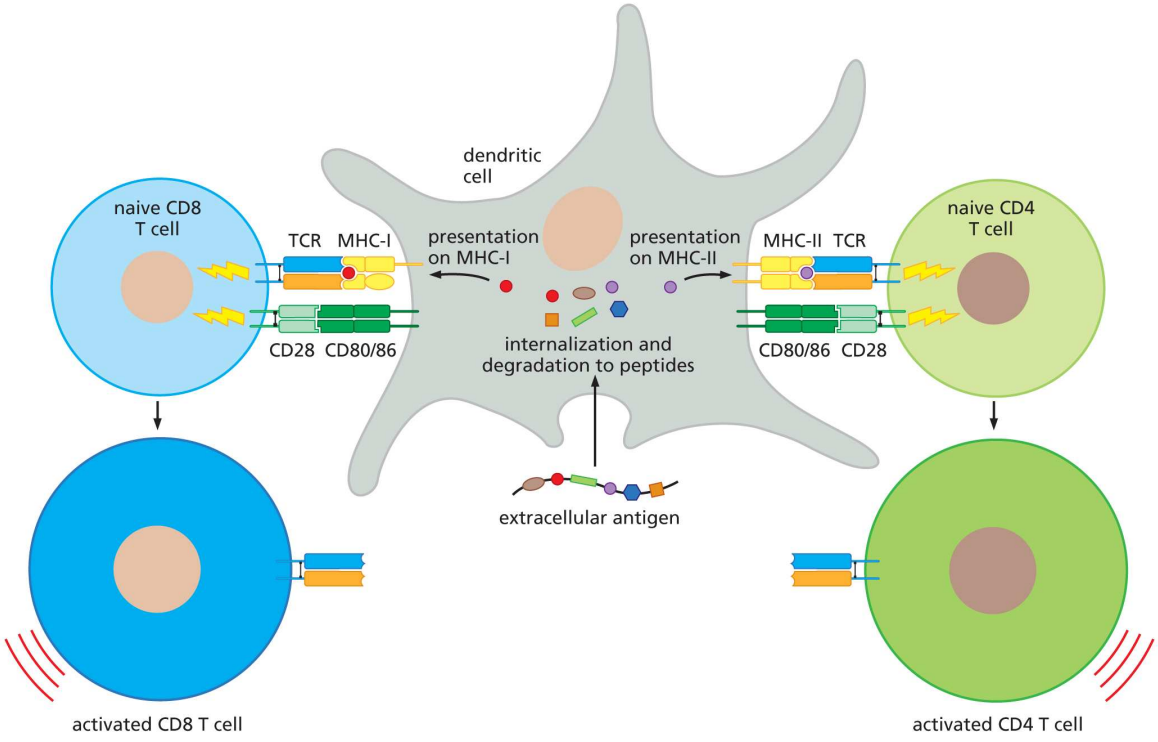
15.7 Dendritic cell activation of naive T cells is a key step in the generation of functional helper and cytotoxic T cells

As mentioned earlier, continuous sampling of the body's tissues is a signature capacity of the dendritic cell (DC) lineage. Having acquired fragments of cells, cellular debris, and pathogens in whatever tissue locations they happen to be found, these versatile cells then migrate with their cargo to nearby draining lymph nodes, that is, to the lymph nodes that are connected directly via lymph ducts to the tissue sites of antigen acquisition (see Figure 14.36).

After arriving in these nodes, the DCs encounter naive T cells that have traveled to these nodes via a totally independent route—the bloodstream; naive T cells by definition have not experienced contact with an antigen and undergone a resulting activation step.

The two routes of travel—via the lymph ducts and the bloodstream—dictate that in most instances, naive T cells that are destined to eventually launch anti-tumor responses do not initially encounter tumor antigens directly in the tumor itself. Instead, this encounter occurs in lymphoid tissues at sites physically removed from the tumor, where peptides derived from proteolysis of tumor cell debris or components are presented on the surface of DCs as peptide:MHC complexes.

In fact, DCs have the unusual ability to present peptides derived from the proteolysis of proteins on both their MHC-I and MHC-II molecules. Thus, they can present peptides from their own native internal proteins on their MHC class I molecules (like all other cells). DCs can also present peptides derived from previously scavenged (that is, foreign) proteins on their MHC-I molecules. Hence, the MHC-I molecules of DCs are employed to present peptides of both native and foreign origin. This unusual ability of DCs to concomitantly present acquired peptides on both sets of MHC molecules is called cross-presentation. This ability is central to the generation of CD4 helper T cells and cytotoxic CD8 T cells (**Figure 15.11**).



The activation of naive cells by contact with a dendritic cell that has ingested an extracellular antigen. The process involves the internalization and degradation of the antigen into peptides, the presentation of these peptides on an M H C complex, and the binding of that complex to a T cell receptor on a T cell in parallel with the binding of a C D80 slash 86 on the dendritic cell to a C D 28 on the T cell. Peptide presentation by M H C 1 activates C D 8 T cells, while Peptide presentation by M H C 2 activates C D 4 T cells

Figure 15.11 Dendritic cells employ cross-presentation to present extracellular antigens to both CD4 and CD8 T cells As described in Figure 15.8, proteins acquired through phagocytosis, endocytosis, or pinocytosis by dendritic cells (DCs) can undergo proteolysis and generate peptides, some of which are presented on the cell surface as peptide:MHC-I complexes to CD8 T cells (*blue, left*), whereas others are presented as peptide:MHC-II complexes to CD4 T cells (*green, right*). This concomitant presentation by two classes of MHC molecules is termed cross-presentation. Although the detailed cell biology of cross-presentation is complex and still unclear, the result is the capacity of DCs to present peptides derived from acquired antigens to both CD4 and CD8 T cells. As indicated in the figure, the amino acid sequences of the peptides presented following binding to MHC-I are different from those presented by MHC-II molecules.

OceanofPDF.com

Glossary

draining lymph node
: A lymph node that receives cells and debris via a lymph duct that drains lymphatic fluid from a specific tissue or sector of a tissue.

naive
: Referring to immune lymphocytes that have not experienced contact with cognate antigens and have not, as a consequence, undergone the biological activation associated with such contact.

cross-presentation
: The presentation by antigen-acquiring cells, notably dendritic cells, of peptides acquired from other cells and cellular debris on the MHC-I cell surface molecules of the antigen-acquiring cells; such presentation occurs concomitantly with peptide presentation by these cells via their MHC-II molecules.

OceanofPDF.com

15.8 Tumor antigens are targets of the immune response to cancer

The above discussions lead inevitably to the questions surrounding the nature of the antigens recognized by the adaptive immune system. In most human tumor types, somatic mutations of cellular genes produce cell-heritable changes in the genomes of cancer cells, some of which result in structurally aberrant cell proteins. A subset of the novel proteins generated by these mutations, such as those creating *ras* oncogenes, may provoke an immune response, in which case they may be called neoantigens, a term implying both their newness and the fact that they were not the objects of tolerance developed during early immune system development.

The presence of neoantigens can be demonstrated experimentally by taking cells that are suspected of expressing them, implanting such cells in an appropriate mouse host, removing or killing these cells, and then determining whether this initial exposure has effectively immunized the host against subsequent implantation with the same strain of tumor cells. This secondary implantation of tumor cells involves live tumorigenic cells and the process of secondary implantation is used to “challenge” the immune system of such mice to determine whether long-term immunity against these cells was actually developed following the initial implantation. (Such an experiment testing for immunity against the cells originating from a particular tumor was described in Section 15.1. We repeat this story in order to emphasize that, at the molecular level, such anti-tumor immunity, if it exists, can be understood only in terms of specific antigens that must have been displayed initially by the immunizing tumor cells as well as by the subsequently introduced, challenging cells.)

In the event that such anti-tumor immunity has developed, the immune systems of the mice initially exposed to these tumor cells will attack the secondarily implanted cells; that is, they will reject these tumor cells. As controls, other lines of cancer cells that were independently induced

previously and unlikely to express the same set of neoantigens can be used to challenge these mice. In principle, exposure to the first population of cells should not confer cross-immunity against the secondarily implanted cells, indicating that the neoantigens displayed by the first populations of cells were *specific* to these cells and not displayed by other independently arising cancer cells or, of course, by normal cells in the body. Such behavior explains the term tumor-specific transplantation antigens (TSTAs), which are implied to be expressed by cancer cells in certain tumors but not necessarily by the cells forming other tumors and not by normal cells throughout the body.

Indeed, tumor-specific antigens may be uniquely expressed by one set of cancer cells and not by any others that are examined thereafter. As should be apparent, these altered proteins are likely capable of inducing certain types of adaptive immune responses.

Note that the proteins resulting from either viral infection or somatic mutation of the cellular genome (as described above) will differ from those encoded by the unmutated genome of the host's cells and therefore fall in the class of tumor-specific transplantation antigens (TSTAs). Because certain TSTAs can be created by randomly occurring somatic mutations, each tumor may display its own TSTA or set of TSTAs; that is, each TSTA will represent a unique immunological marker of the cells in that particular tumor.

Importantly, because TSTAs are not present during the early development of the immune system when immunological tolerance develops, they may well be recognized as foreign entities by the adaptive immune system, and the cancer cells bearing these TSTAs may become objects of immune attack and elimination.

As we have learned (for example, in Chapter 11), most somatically mutated genes formed during the course of tumor progression are unlikely to drive this progression forward, simply because they affect genes whose alteration does not confer advantageous phenotypes on the cells that have acquired such mutant alleles. Instead, as described in Section 11.6, these mutations are categorized as creating mutant *passenger* alleles, in contrast to mutations that affect genes whose alteration is indeed advantageous for cancer cell survival and proliferation and are, in that sense, considered to affect *driver* genes. Thus, the passenger alleles are only "going along for the ride," being present

in cells that happen to have acquired advantageous driver mutations and are undergoing clonal expansion during the course of multi-step tumor pathogenesis.

Both mutant driver and mutant passenger genes may encode neoantigens (**Sidebar 15.5**). Therefore, the fact that an allele is either a driver or a passenger is unrelated to its ability to encode a neoantigen. One example of a mutation that is functionally important for tumor growth and, at the same time, able to create a neoantigen, is the mutation of the gene encoding the normal K-Ras protein into a driver oncogene that encodes a K-Ras oncoprotein (see Section 4.3). Once created, the structurally novel oncoproteins have the potential to generate peptides that may evoke T-cell responses when presented on appropriate MHC molecules.

Sidebar 15.5 Neoantigens encoded by passenger genes have implications for the success of anti-tumor therapies

Most neoantigens expressed by tumor cells are encoded by mutant passenger alleles rather than by driver alleles and are, by definition, not critical to continued cancer cell proliferation and survival. The distinction between the two classes of neoantigens may be functionally critical for the outgrowth of a tumor, in particular its responses to anti-tumor immunotherapy, because cancer cells may attempt to evade immune attack by down-regulating expression of certain neoantigens.

This evasive maneuver raises the question of whether or not cancer cells will pay a price for down-regulating the expression of a particular neoantigen. If the neoantigen is encoded by a mutant driver gene allele, a cancer cell cannot afford to lose this antigenic protein, as its loss is likely to compromise further survival and proliferation of this cell. The contrasting situation pertains to neoantigens encoded by passenger genes: in this instance, a cancer cell may freely shut down expression of the neoantigens without paying a price in terms of its selective fitness. This may, in turn, allow this cell and its progeny to evade further immune attack launched by lymphocytes that previously recognized this neoantigen and, provoked by its display, undertook to eliminate this cell.

As we will learn later, such immunoevasive maneuvers are critically important in determining whether the immune system can sense and eliminate spontaneously arising tumors, thereby preventing their clinical appearance in certain tissues. Similarly, successes of anti-tumor immunotherapy may depend on whether or not targeted tumor cells can down-regulate expression of certain neoantigens, doing so in order to escape therapy-driven killing.

Yet another example derives from the numerous types of chromosomal translocations that lead to fusion proteins (see Section 4.4). Such translocations are frequently found in hematopoietic malignancies, such as chronic myelogenous leukemia (CML). This well-studied translocation, which is created by the fusion of one portion of the *Bcr* gene with a portion of the *Abl* proto-oncogene, generates a novel peptide sequence at the site where the two coding sequences are joined. In fact, the highly immunogenic peptides generated from this novel peptide segment can indeed provoke T-cell responses.

In addition to TSTAs, there are some normal cellular antigens that are associated with certain tumors that may actually attract the attention of the immune system. By implication, expression of these antigens is not limited uniquely to an individual spontaneously arising tumor, and these antigens are therefore not tumor-specific. These antigens are designated as tumor-associated transplantation antigens (TATAs) or more simply called tumor-associated antigens (TAAs), with the implication that such antigens may also be expressed by other cells in the body rather than being unique, novel antigens created during the formation of a single tumor (**Table 15.2**).

Table 15.2 Examples of tumor antigens

Antigen type	**Example**	**Nature of antigen**	**Occurs in indicated cancers**
Oncogenic virus-encoded nonvirion protein	HPV E6 and E7 proteins	Nonstructural oncogenic proteins	Cervical carcinoma

Antigen type	Example	Nature of antigen	Occurs in indicated cancers
Product of chromosomal translocation; gene rearrangements, insertions, or deletions	Bcr-Abl protein	Novel oligopeptide at site of fusion of reading frames of two otherwise unlinked genes	Chronic myelogenous leukemia
Neoantigens	Changes in primary structure resulting from point mutations in *Ras* Changes in primary structure of P53 resulting from any of many dozens of alternative point mutations in *p53* Point mutations that alter	Oncogene generated by mutation of proto-oncogene counterpart Alternative amino acid substitutions at sites within or outside of DNA-binding domain Novel protein sequences conferring potential T-cell-recognized epitopes	Many types of cancerMany types of cancer Many types of tumors with distinctive landscapes of mutationally generated neoepitopes

Antigen type	Example	Nature of antigen	Occurs in indicated cancers
	primary structures of diverse cellular proteins		
Differentiation antigens	Tyrosinase PSMA	Enzyme in melanin synthesis pathway Cell surface protein with carboxypeptidase activity expressed by cells of prostatic epithelium	MelanomaProstate cancer
Cancer testis antigens	MAGE-1MAGE-3 NY-ESO	Protein normally expressed in testes; aberrantly expressed in several types of cancer Protein normally expressed in testes; aberrantly expressed in several types of cancer	Melanoma, NSCLC, esophageal carcinoma

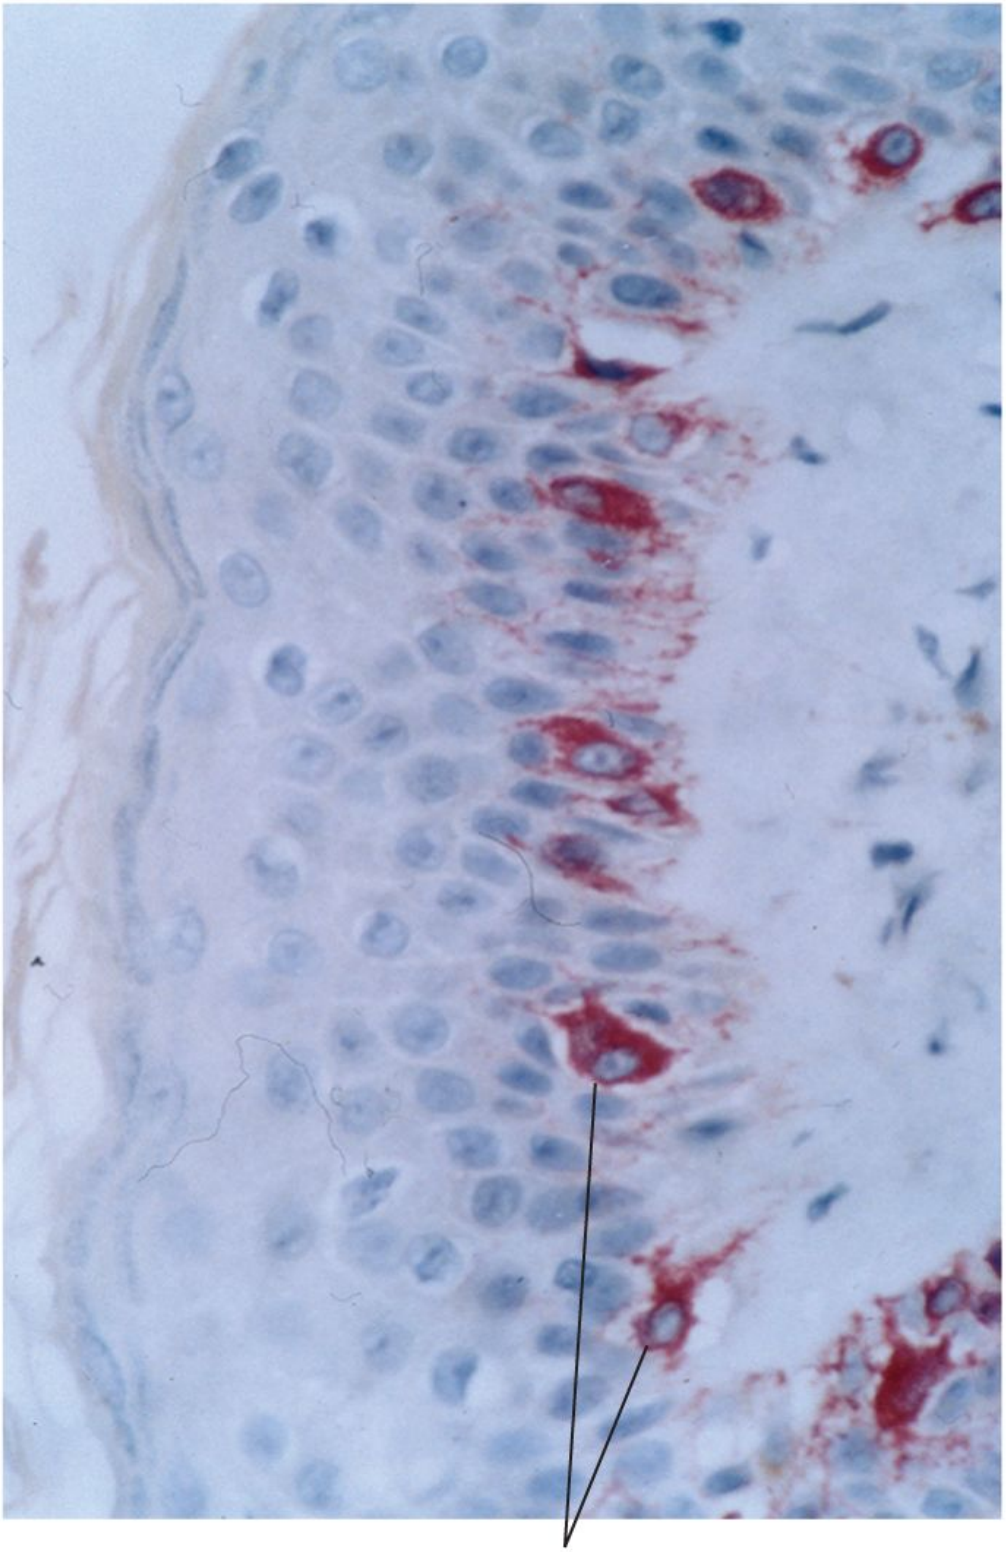
Antigen type	Example	Nature of antigen	Occurs in indicated cancers
Overexpressed antigens	HER-2 MUC-1WT1	Receptor tyrosine kinase expressed on epithelial cell surface Glycosylated protein found on epithelial surfaces Transcription factor	Breast cancer, ovarian cancer Breast cancerPancreatic cancerLeukemia
Abnormal post-transcriptional modification	NA17	Abnormal protein resulting from retention of introns during splicing of pre-mRNA	Leukemia

Adapted from K. Murphy, C. Weaver and L. Berg (eds.), Janeway's Immunobiology 10th ed. New York: W. W. Norton & Company, Inc., 2022.

The ability of an immune system to focus on a TATA will depend, by necessity, on whether tolerance has been developed by the immune system of the tumor-bearing host. For example, such tolerance may not have been developed, as discussed earlier, simply because the particular normal antigen was expressed in a tissue, such as the testis, that is shielded from intensive immunosurveillance and therefore did not participate in the generation of immune tolerance early in the development of the immune system. Other TATAs may derive from proteins that are normally expressed only transiently during early embryonic development, long before the functional immune

system and associated tolerance have been established. For example, MAGE, a protein expressed in normal cells of the testes, is expressed in certain melanomas and will behave as a TATA (see Table 15.2; **Figure 15.12**). Because certain TATAs are plausibly expressed by a variety of normal cells in the tissues of a tumor-bearing host, an immunotherapy directed against them may often result in unacceptably high levels of therapy-associated toxicities.

tyrosinase antigen

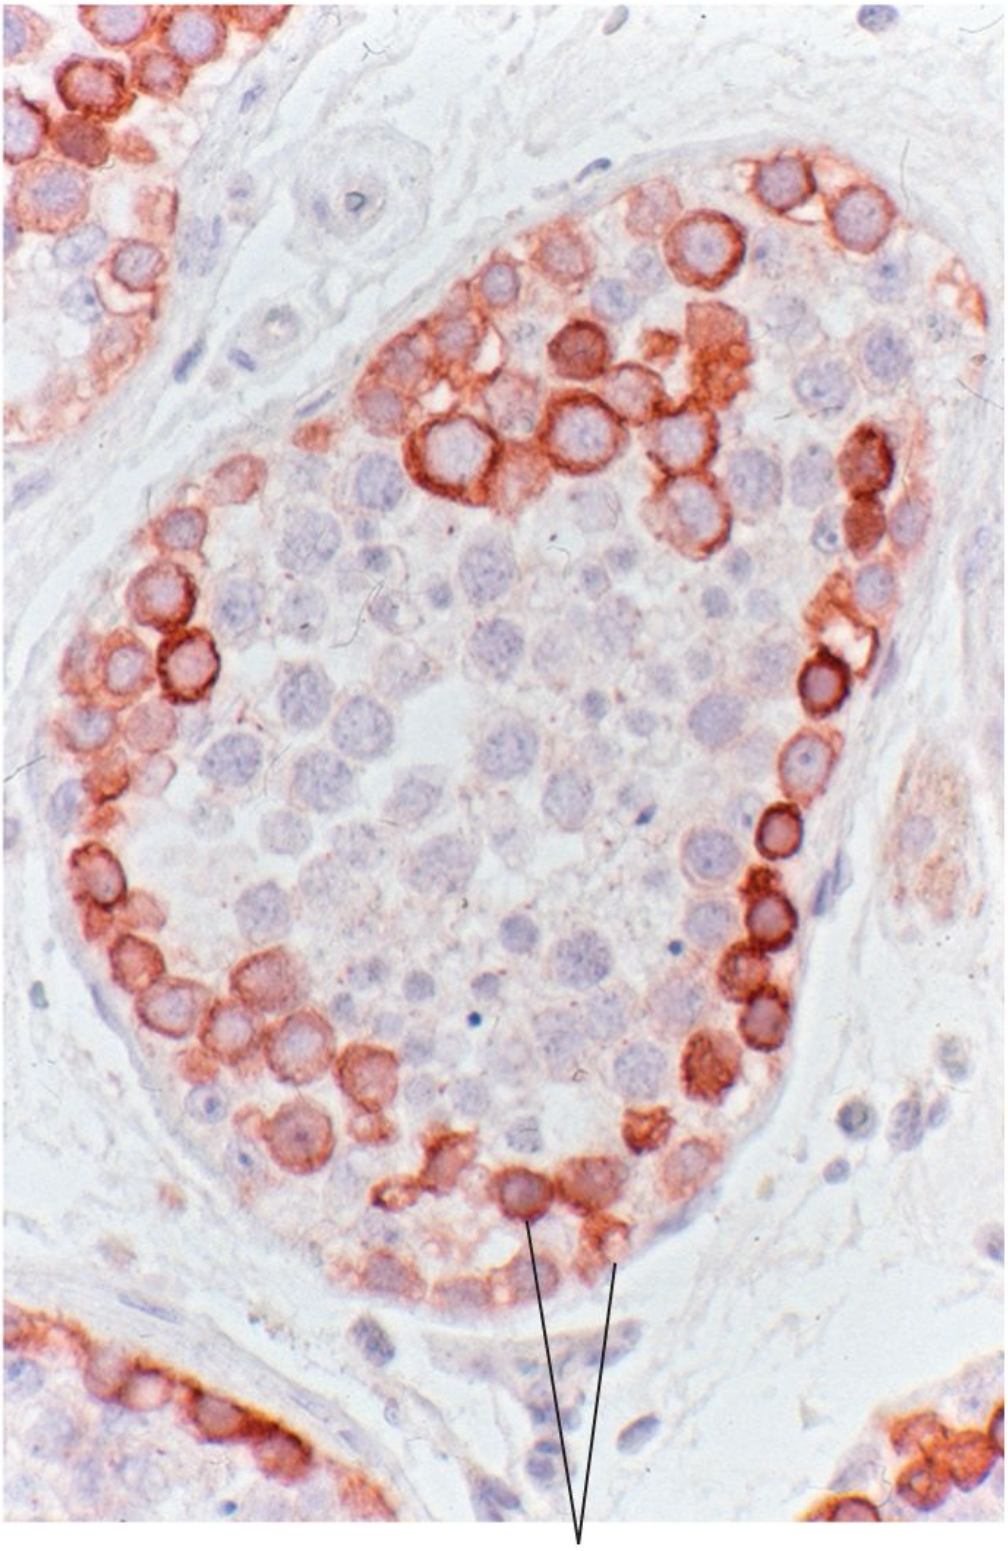


skin melanocytes

The image, titled tyrosinase antigen, is a histology stain image of skin tissue in which most cells appear pale blue with darker blue nuclei, but a few isolated cells appear in red. These are labeled as melanocytes.

(A)

MAGE-1 antigen



testes

spermatagonia

The image, titled M A G E-1 antigen, is a histology stain image of testes tissue in which a cluster of round, pink cells is surrounded by lighter tissue. Many of the cells near the perimeter of the cluster have darker cell walls than those close to the center. These darker cells are labeled as spermatogonia.

(B)

Figure 15.12 Normal proteins displayed as tumor-associated melanoma antigens (A) A monoclonal antibody has been used here to detect the enzyme tyrosinase, which is involved in pigment production in melanocytes and melanomas. Though present in melanocytes (*dark red*) this enzyme is not detectable in other normal tissues. Its expression by melanoma cells can cause them to become immunogenic and the targets of killing by CTLs. (B) The spermatogonia in the testes have been stained here with a monoclonal antibody against the MAGE-1 antigen (*red*); normally this antigen is only seen in one additional site—the placenta. Its expression has been detected in a variety of human tumor types and has been studied in detail in melanomas because it is often immunogenic when expressed by these tumors. (A, from Y.T. Chen et al., *Proc. Natl. Acad. Sci. USA* 93:5915-5919, 1996. With permission from National Academy of Sciences, U.S.A. B, from J.C. Cheville and P.C. Roche, *Mod. Pathol.* 12:974–978, 1999. With permission from Nature.)

Some of the TATAs may be expressed as domains of cell surface proteins. For instance, normal B cells display a protein called CD20 that is also present as a TATA in many B-cell lymphomas that derive from the normal B-cell compartment of immune cells. In theory, TATAs like CD20 could be used as targets to provoke and guide attacks by the immune system on lymphoma cells that express CD20. However, such attacks rarely happen spontaneously because normal cell proteins like CD20 are shielded by immune tolerance.

We should note that the spontaneous targeting of various normal self-antigens by a host immune system (which could lead to autoimmune conditions) is the rare exception rather than the dependable rule, as might be predicted from the usually efficient actions of the tolerance-inducing mechanisms operating in the immune system. However, in the next chapter we will discuss the

deployment of technologies that are indeed capable of enlisting a variety of self-antigens as useful targets for innovative anti-cancer immunotherapies. Table 15.2 lists a variety of TATAs that have been identified in human tumors.

OceanofPDF.com

Glossary

neoantigen
: An antigen that is newly formed by tumor cells, usually during the course of tumor development, and is created by somatic mutations affecting the reading frames of cellular mRNAs.

tumor-specific transplantation antigen
: An antigen that can, through transplantation analyses, be associated with one particular tumor cell population but not with other similar tumor cell populations. *See also* **tumor-specific antigen**.

tumor-associated transplantation antigen
: An antigen encoded by a normal cellular allele that is expressed by a certain class of tumors and may have, for various reasons, not elicited immune tolerance. *See also* **tumor-specific antigen**.

tumor-associated antigen
: An antigen that is associated with the cells of a tumor and may also be displayed by normal cells or tissues throughout the body; *also termed* **tumor-associated transplantation antigen**. *Compare* **tumor-specific antigen**.

15.9 Natural killer cells contribute to anti-cancer immunity

Cytotoxic T cells are the most formidable weapons that the immune system deploys in the struggle to eliminate cancer cells. Confronted by the strong selective pressure applied by CTLs, it is not surprising that some cancer cells might contrive to shut down display of their class I MHC molecules, thereby depriving CTLs of the peptide:MHC complexes needed by the CTLs to recognize (via their TCRs) these cancer cells and target them for killing. Such down-regulation, like the down-regulation of TATAs described above, may allow cancer cells to elude CTL-mediated death.

Natural killer cells (NK cells) can block this potential avenue of escape from killing. These lymphocytes operate as key components of the innate immune system that are programmed to kill cells throughout the body that fail to display normal levels of MHC-I molecules (independent of the presence or absence of tumor antigens). During the evolution of the immune system, the development of NK cells was clearly selected in order to anticipate immune-evasive maneuvers undertaken by cells infected with viruses and certain other intracellular pathogens.

NK cells kill target cells by releasing cytotoxic granules similar to those released by CTLs. In addition to mounting cytotoxic granule–mediated attack, NK cells also produce interferon γ (IFN-γ), a key inflammatory cytokine that favors cell-mediated immunity by stimulating the up-regulation by potential target cells of class I MHC expression, thereby making the targeted cells more vulnerable to CTL attack.

In fact, potential target cells can display other outward-facing indicators that they are, in one way or another, aberrant and thus appropriate targets for elimination by components of the innate immune system. Specifically, the display of stress-induced ligands on the cell surface of cancer cells can be detected by an NK-cell receptor known as NKG2D. These ligands appear to be induced by a variety of cellular stressors, including genetic damage caused by radiation or chemical agents, viral infections, and neoplastic transformation. The NK cell surface receptor NKG2D interacts with these stress-induced ligands on potential target cells, and the resulting interaction, like the one triggered by inadequate levels of MHC-I molecules, results in strong activation of an NK cell's cytotoxic response.

In addition to the surveillance provided by the NKG2D receptor, an additional family of receptors, generically termed KIR (*K*iller *I*mmunoglobulin-like *R*eceptors), also

monitors the levels of certain MHC-I molecules; many of these KIRs *inhibit* NK function if the levels of the MHC-I molecules are relatively normal and, conversely, *allow* NK-mediated killing if MHC-I levels slip below a certain threshold.

Finally, an important alternative avenue of NK cell killing involves the cooperative interaction of components of the innate and adaptive immunity systems. This mode of killing depends on the binding of antibody molecules directly to cell surface molecules displayed by potential target cells, such as cancer cells. The cell surface display of these molecules (which are tethered directly to the plasma membrane) reflects their normal localization and does not in any way involve MHC-I molecules as agents of antigen presentation.

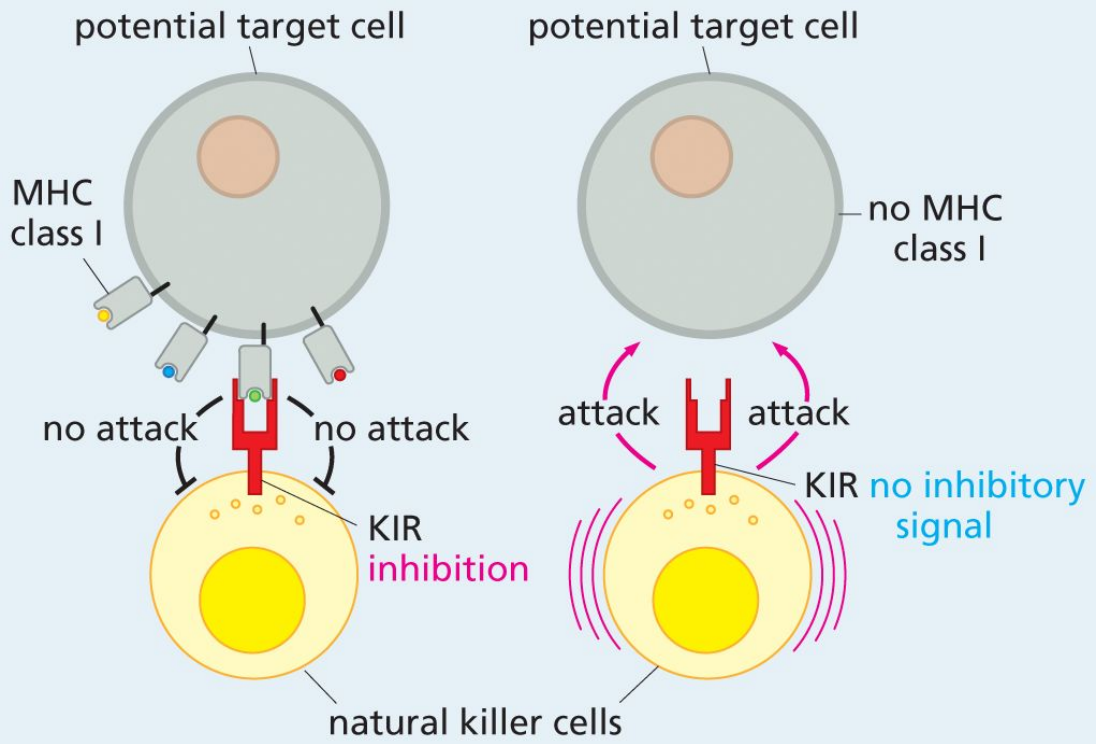
NK cells, as agents of innate immunity, bear Fc receptors—a class of receptors that recognize and bind the constant (Fc) region of common antibody molecules. A chance encounter between NK cells and a cell whose surface is studded, even partially, by antigen-bound antibody molecules may, on its own, trigger NK cell–mediated killing of the antibody-coated cell. This process is known as antibody-dependent cellular cytotoxicity (ADCC; **Sidebar 15.6**). Many of the activities of NK cells are summarized in **Figure 15.13**.

Sidebar 15.6 Antibody-dependent cellular cytotoxicity (ADCC) is a major pathway of antibody-mediated killing

ADCC has attracted great interest over the past two decades, largely because of the development of monoclonal antibodies (mAbs) that bind antigens displayed on the surface of various types of tumor cells. This binding, in turn, can trigger the killing of the antibody-bound cells, often through the actions of NK cells. The killing process reflects a mechanism of antibody-dependent cellular cytotoxicity that is normally operative in the body and depends on naturally arising antibody molecules that bind cell surface proteins expressed by various cells. As an example, many RNA virus particles are cloaked in a lipid bilayer from which virus-encoded glycoprotein spikes protrude. These spikes, which engender an antibody response in infected individuals, are also expressed on the surface of virus-infected cells. As a consequence, such cells may attract antiviral antibody binding and, in turn, become victims of ADCC. Such an ADCC response also may be triggered by mAbs that are introduced into the body as part of an anticancer immunotherapy.

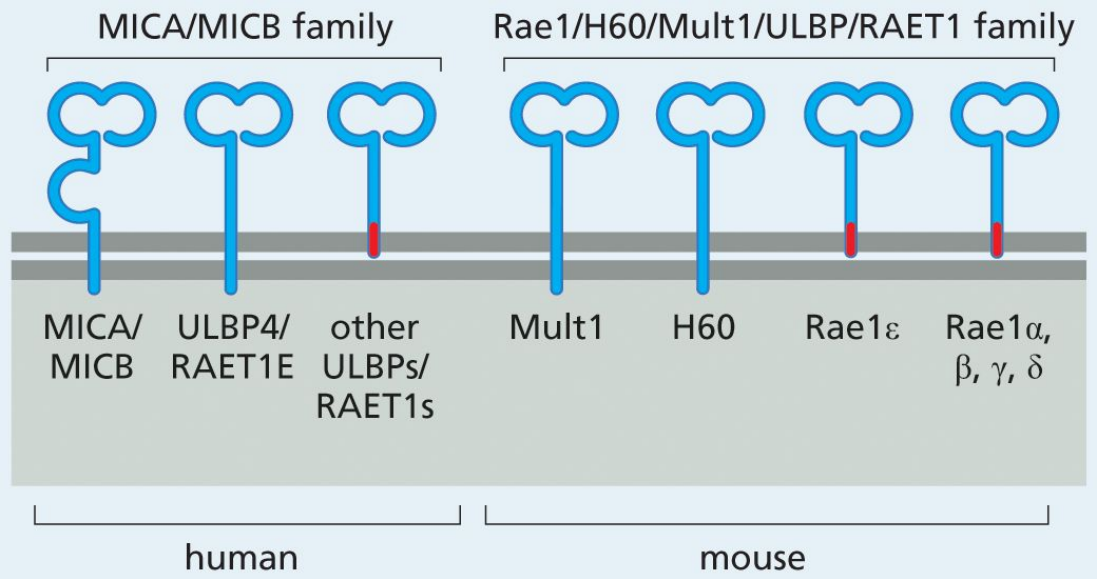
ADCC, as it operates naturally within the body, represents a convergence of the adaptive immune system, which forms antigen-binding antibodies, and the innate immune system, represented by NK cells that recognize antibody-coated cells. In more detail, many NK cells express on their surface the Fcγ receptors (FcRγ) that bind the constant (C) regions of antibody molecules that are already bound via their V regions

to cell surface antigens. One direct consequence is the activation of a cytotoxic attack by the NK cells on the antibody-coated cells, which results in the death of the latter. The killing mechanisms depend, as cited earlier, on the exocytosis by NK cells of cytotoxic granules, including those carrying granzymes that trigger the rapid death of the antibody-bound cell.



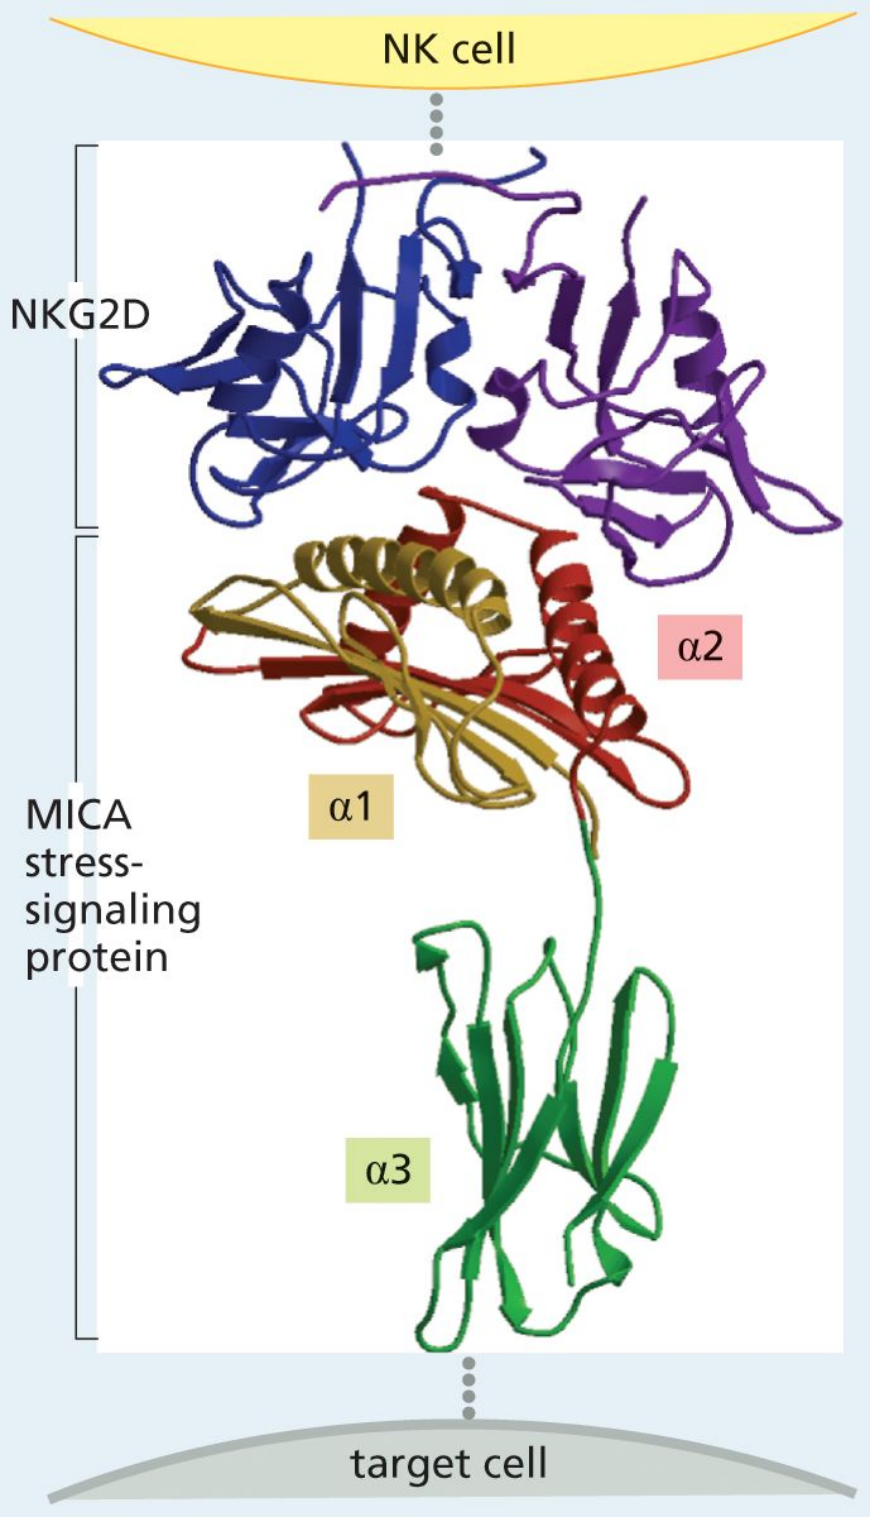
Two natural killer cells, each paired with a potential target cell. On the left, the target cell is studded with M H C class 1 molecules. One of them binds to a K I R on the killer cell, triggering an inhibitory signal that prevents the killer cell from attacking. The target cell on the right, not displaying any M H C class 1 molecules, is attacked because there is no inhibitory signal.

(A)



Seven surface alarm proteins, displayed side by side. The first three belong to the M I C A slash M I C B family and are found in human tissue. The last four belong to the Rae 1 slash H 60 slash Mult 1 slash U L B P slash R A E T 1 family and are found in mouse tissue.

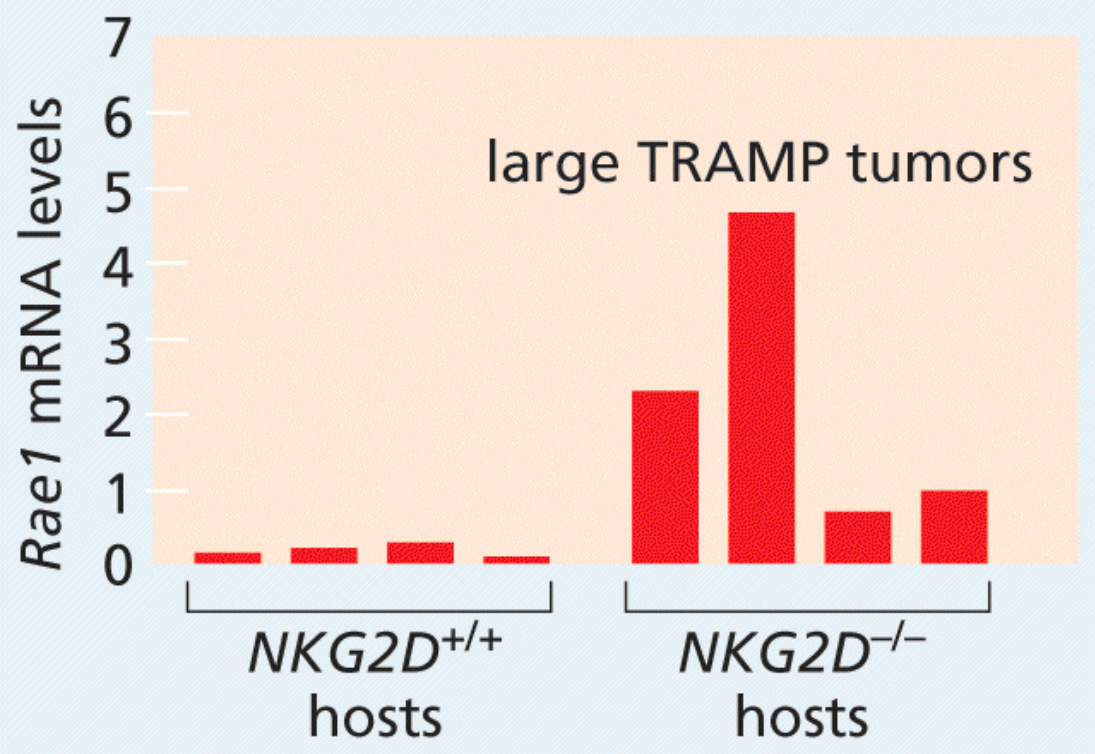
(B)



A ribbon diagram of a complex formed by N K G 2 D and an M I C A stress signaling protein that consists of alpha 1, alpha 2, and alpha 3 units, where the alpha 1 and alpha 2 units bind to the N K G 2 D. The complex is part of a

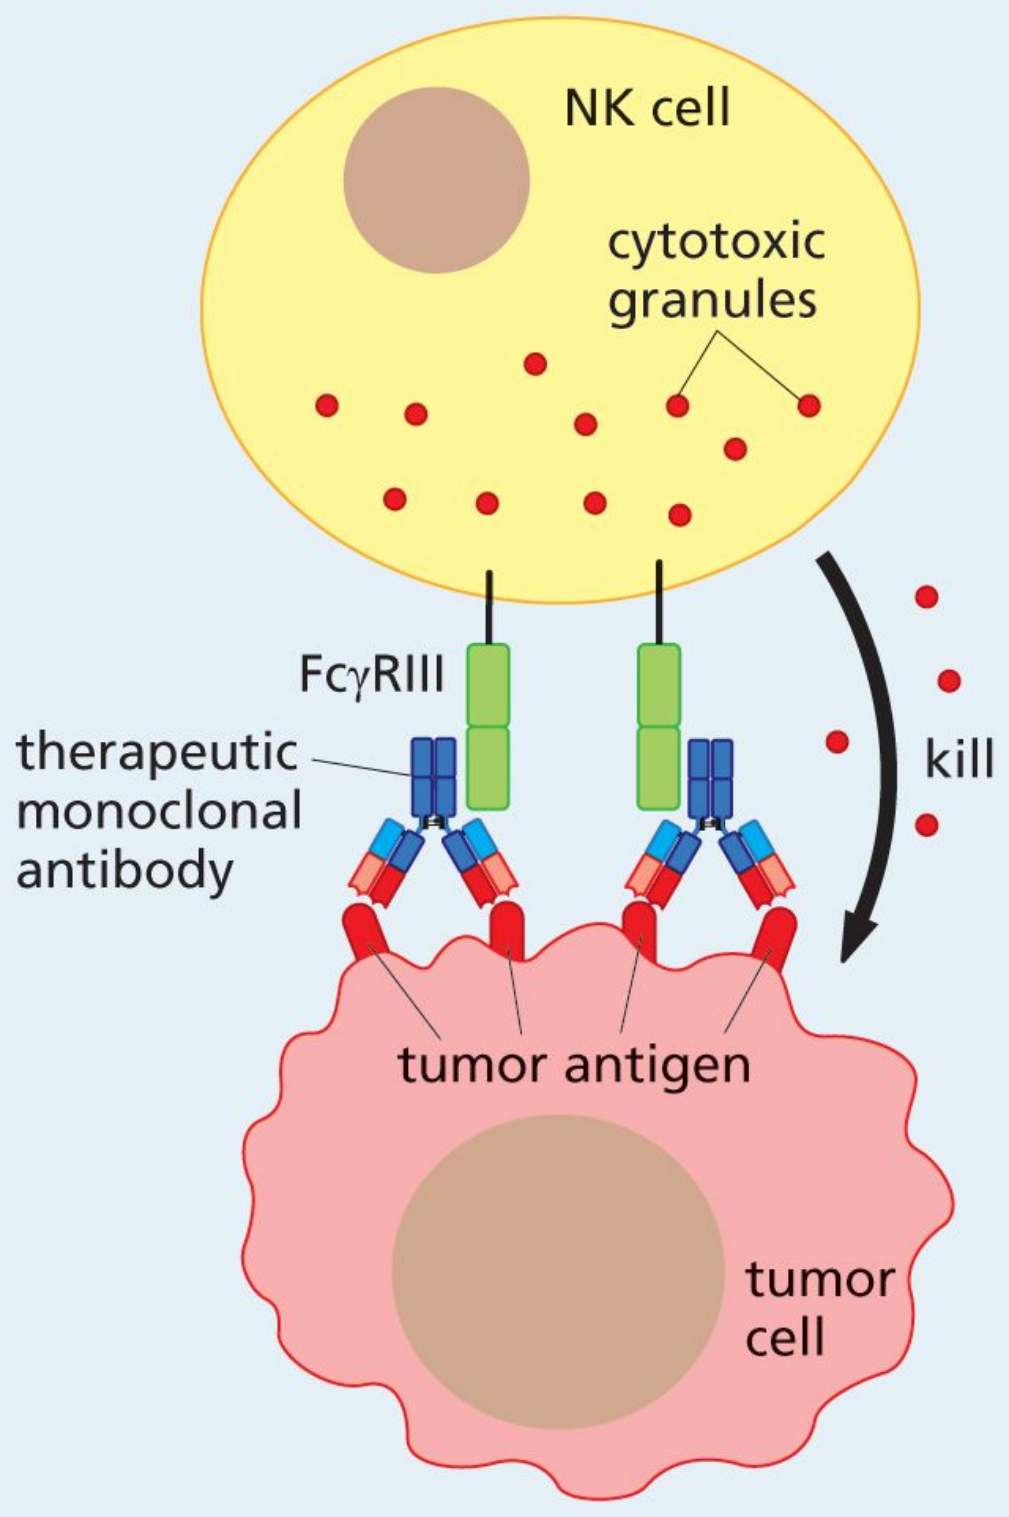
bridge between a natural killer cell and a target cell. The N K G 2 D end of the complex is oriented toward the killer cell.

(C)



A bar graph showing R a e 1 m R N A levels in eight hosts. The first four hosts are homozygous N K G 2 D positive. R a e 1 m R N A levels are uniformly low. The last four hosts are homozygous N K G 2 D negative. The R a e 1 m R N A levels are higher, and considerably so in two of the four cases. These cases present large TRAMP tumors.

(D)



A tumor cell and a natural killer cell. Therapeutic monoclonal antibodies attach with their arms to antigens displayed by the tumor and with their bases to F c gamma R 3 receptors on the killer cell. This linkage of the two cells

triggers a release of cytotoxic granules from inside the killer cell; these attack the tumor cell and kill it.
(E)

Figure 15.13 Control of killing by natural killer cells is mediated by inhibitory and activating signals (A) Natural killer (NK) cells display *inhibitory* receptors that can recognize MHC class I molecules being displayed on the surface of cells. When MHC-I molecules are present at levels above a threshold, these inhibitory receptors (*red*) provide negative signals that discourage NK-mediated cell killing. One class of inhibitory receptors are those of the KIR (*K*iller *I*mmunoglobulin-like *R*eceptor) family, which recognize some MHC-I molecules but not others. Another type is CD94–NKG2A, a heterodimer (*not shown*). In both cases, recognition by NK cells of MHC-I molecules displayed by a nearby potential target cell can dampen or block NK-mediated attack (*left*); this recognition of MHC-I molecules can be achieved by one or the other and sometimes both types of these inhibitory receptor types displayed by the NK cell. In the absence of such recognition and functional silencing by either of these inhibitory receptors, NK-mediated attack is unimpeded (*right*). (B) In contrast to the actions of these inhibitory receptors, other NK-associated receptors are involved in *activation* of NK cells by proteins; as in (A), this type of response is triggered by cell surface proteins displayed by potential target cells. Thus, when many types of cells are suffering certain types of cell-physiological stress, they may display alarm proteins on their surface. Notable causes of such stresses include genetic damage, viral infection, and neoplastic transformation. Shown here is a series of frequently displayed human and mouse cell surface alarm proteins (*blue*). (C) Seen here are ribbon diagrams of the molecular structures of the components of the complex formed between NKG2D, an NK-associated homodimeric receptor (*light purple, dark purple, above*) and its cognate ligand, the MICA alarm protein displayed by a human cell, such as a cancer cell (α*1brown,* α*2magenta and* α*3green, below*), under stress. (The domains that anchor these various proteins to the surfaces of the NK and the target cell are not shown.) (D) Tumor cells arising in the TRAMP transgenic mouse model of prostate adenocarcinoma development express on their surface the Rae1 alarm ligand (see panel B), which serves as an activating ligand for the NKG2D receptor displayed by NK cells. The tumor cells formed in TRAMP host mice that carry wild-type versions of the NKG2D-encoding gene expressed low levels of *Rae1* mRNA. In contrast, in TRAMP host mice in which the *Klrk1* gene encoding NKG2D had been knocked out, the tumor cells expressed far higher levels of the *Rae1* transcript. This suggests that TRAMP tumor cells can down-regulate their Rae1 expression in order to avoid attack and elimination by the NK cells that display NKG2D. (E) The binding of FcγRIII receptors displayed by NK cells to antibodies previously bound to antigens displayed on the surfaces of potential

target cells (represented here by a tumor cell), causes the directed release of cytotoxic granules from the NK cell into the target cell, resulting in the death of the latter; this process is termed antibody-dependent cytotoxicity (ADCC). 15.10 Macrophages make multiple contributions to tumor development

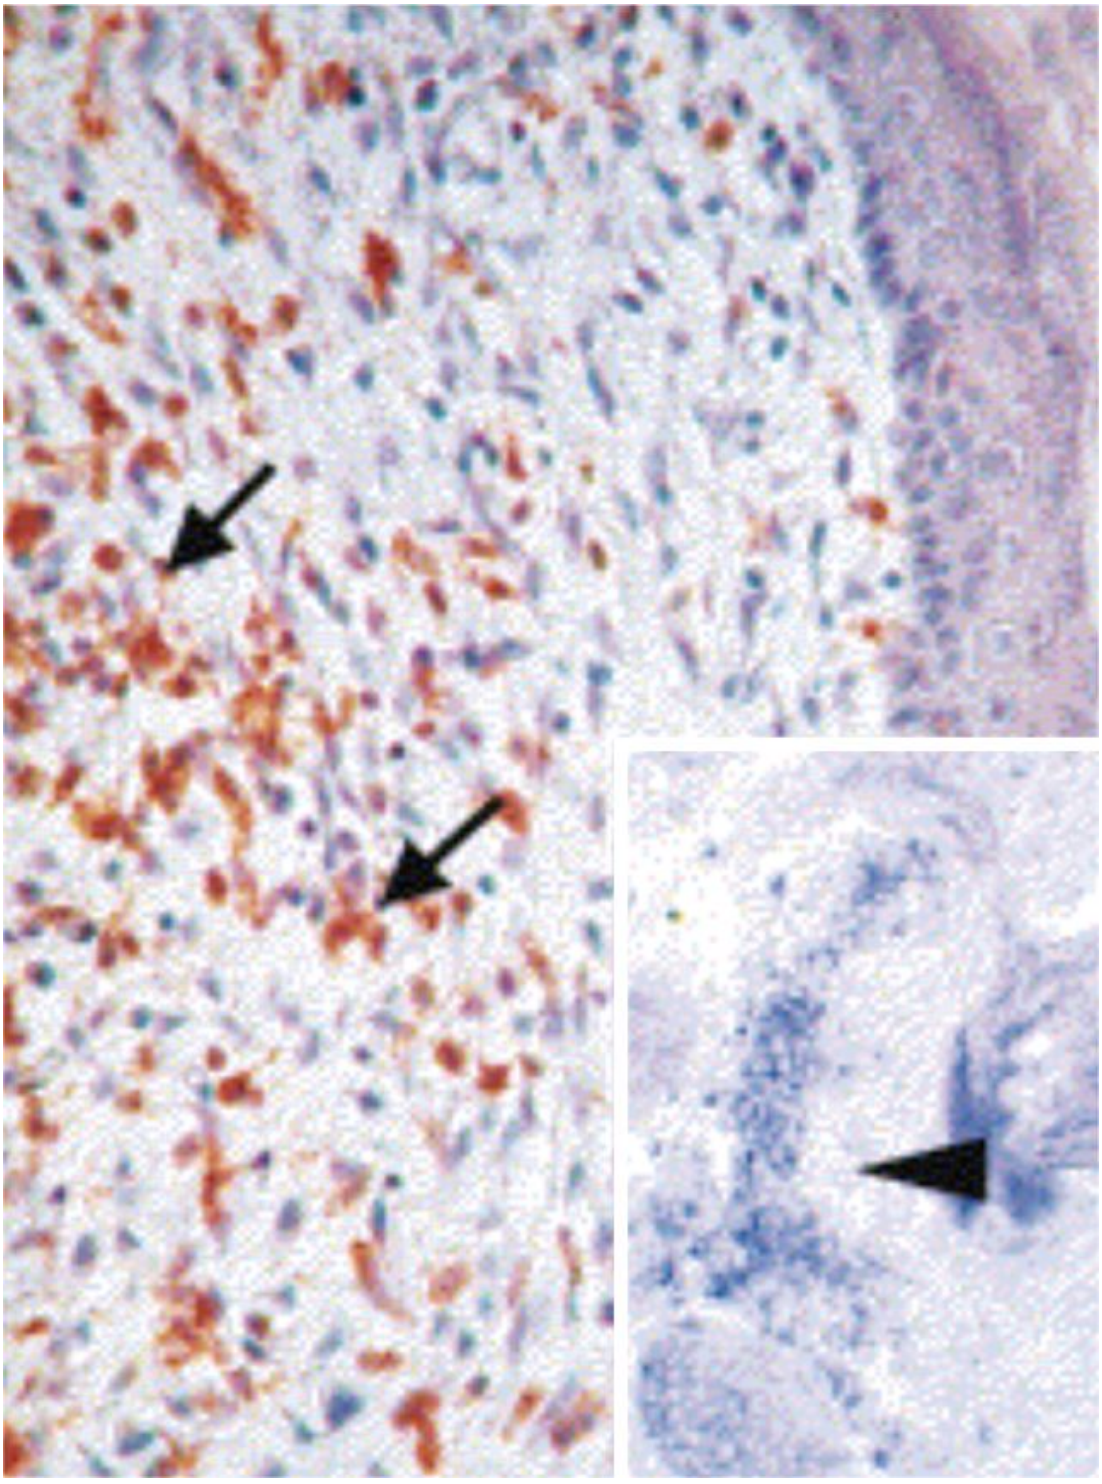
Macrophages represent a category of versatile phagocytic cells that are also involved in tissue repair and often secrete cytokines capable of directing and modifying the behavior of a variety of other cell types. They are essential cellular elements of innate immunity and exist in a range of specialized, functionally activated states that span a spectrum of alternative phenotypes. These phenotypes are often described, simplistically, as ranging from the M1 state at one pole of a spectrum of phenotypes to M2 at the other.

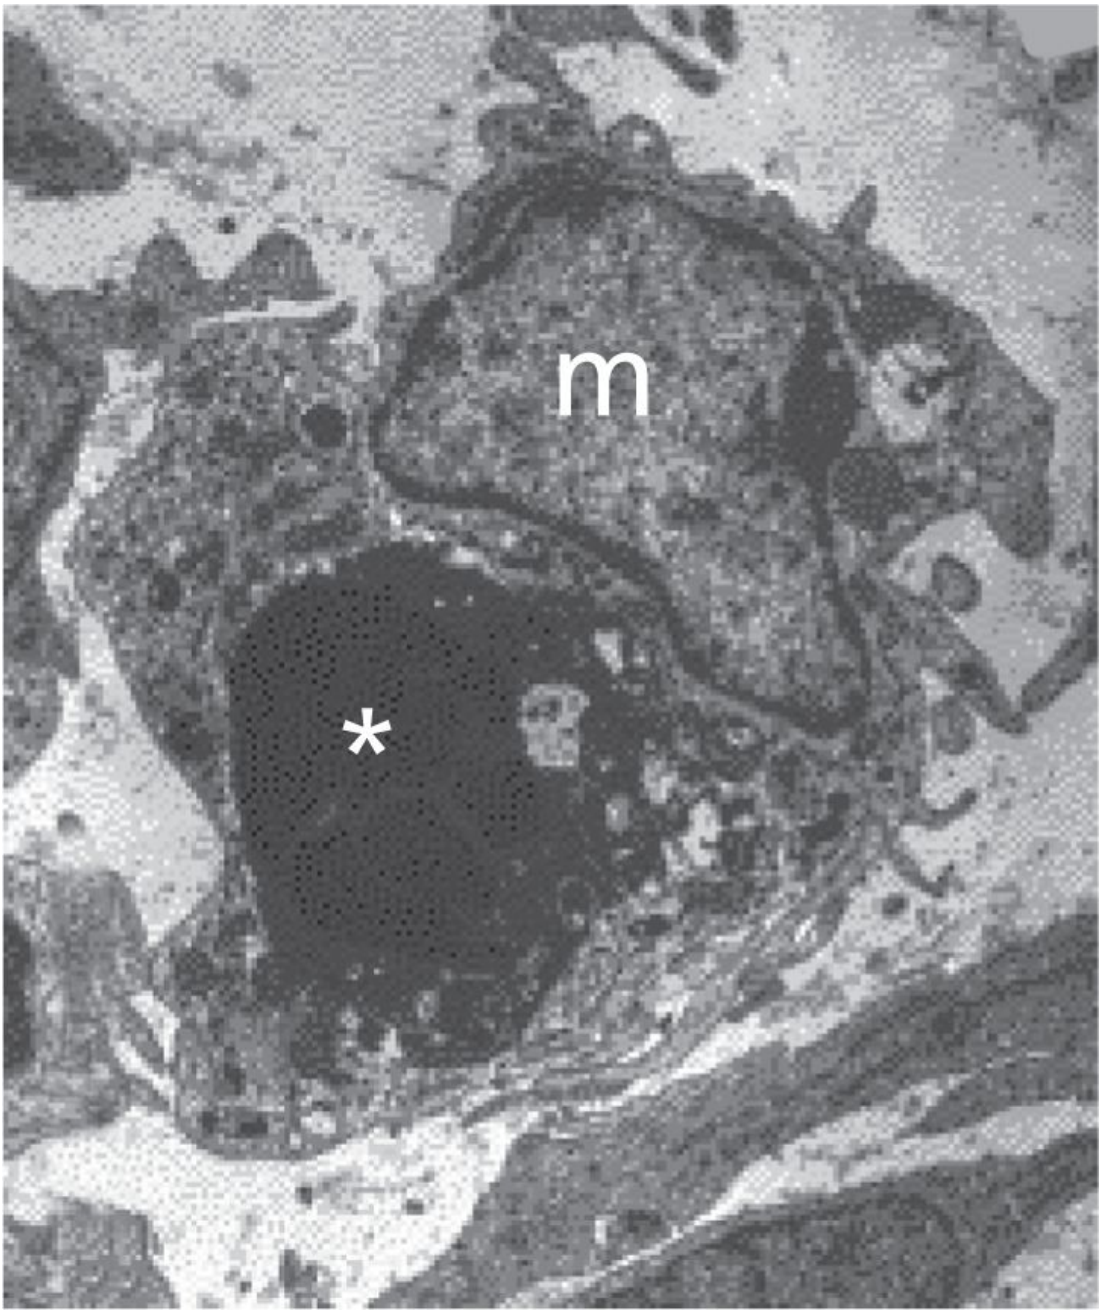
To focus on the salient traits of the macrophages: cells in the M1 state are cytotoxic and highly phagocytic, and they can produce IL-12, a cytokine that supports the generation of one subset of helper T cells termed T_H1. In the context of cancer pathogenesis, these attributes favor tumor control and elimination. In contrast, macrophages in the M2 state (sometimes referred to as alternatively activated macrophages) produce IL-10 and TGF-β, both of which are immunosuppressive cytokines and, accordingly, protect cancer cells from immune attack, thereby favoring tumor persistence and progression. The M2 macrophages also favor tissue repair and regeneration, support vascularization by secretion of VEGF (see Section 13.5), and secrete proteases that contribute to tissue remodeling.

Actually, most macrophages do not reside at the extreme poles of the M1/M2 spectrum of phenotypes. Instead, depending on conditions, many adopt phenotypes that are aligned more toward one or the other of these states and thus enter mixed phenotypic states located at various intermediate positions along this spectrum. Accordingly, the extent to which macrophages contribute to tumor control and elimination or, alternatively, to tumor maintenance and progression, depends on where they reside along this continuum of phenotypes. Some of the many roles played by macrophages in normal and tumor physiology are illustrated in **Figure 15.14**.



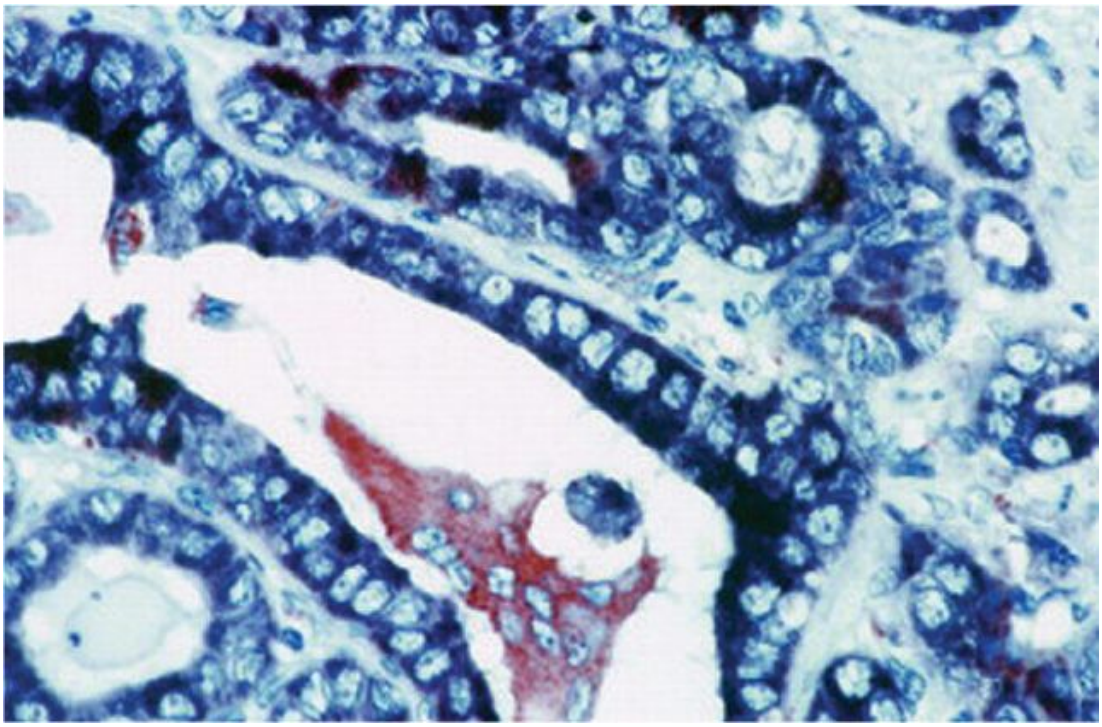
A histology stain image of bluish skin tissue containing many brown macrophages. An inset shows a curving band of dark blue spots surrounded by light blue tissue.

(A)



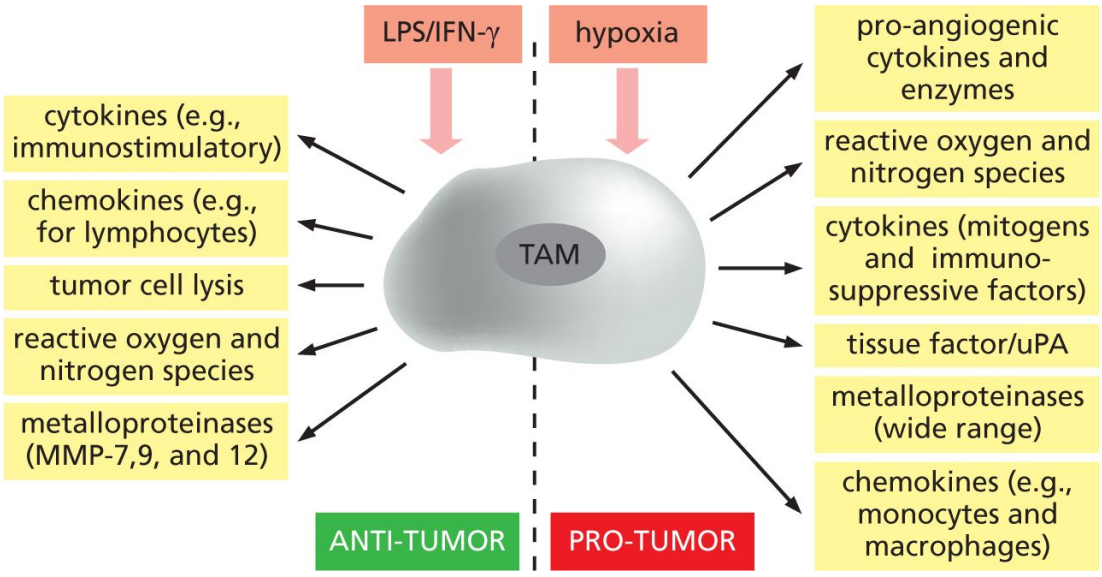
A black and white image of a cell labeled m that engulfs a large, dark object labeled with an asterisk.

(B)



A histology stain image. The tissue is mostly dark blue, but in the lower middle, where there is white space, a pinkish cell is in the process of engulfing a smaller dark blue one.

(C)



A graphic lists two sets of functions that a tumor-associated macrophage is capable of. Exposure to lipopolysaccharide or interferon gamma induces anti-tumor functions such as cytokines (e.g., immunostimulatory); chemokines

(e.g., for lymphocytes); tumor cell lysis; reactive oxygen and nitrogen species; and metalloproteinases (MMP-7,9, and 12). Hypoxia, on the other hand, induces pro-tumor functions such as pro-angiogenic cytokines and enzymes; reactive oxygen and nitrogen species; cytokines (mitogens and immunosuppressive factors); tissue factor slash u P A; metalloproteinases (wide range); and chemokines (e.g., monocytes and macrophages).
(D)

Figure 15.14 Multiple roles of macrophages Macrophages play critical roles in promoting wound healing and tumor progression. They also act in an opposing fashion as agents of the immune system to present tumor antigens and to consume tumor cells. These different functions are carried out by distinct subtypes of macrophages. (A) In this wound-healing site in the skin of a mouse, macrophages (*brown*) are detected in abundance (*arrows*) through use of immunochemical procedures that recognize the F4/80 macrophage-specific antigen and the CSF-1R receptor marker (*arrowhead, inset*). (B) Transmission electron microscopy reveals a macrophage (m) that is engorged with the phagocytosed corpses of apoptotic cells (*asterisk, dark body*) in the middle of a wound-healing site. (C) A macrophage (*pinkish*) is seen as it begins to phagocytose a tumor cell in the lumen of a duct within a papillary thyroid carcinoma. (D) Macrophages can be activated by diverse signals, such as interferon-γ (IFN-γ) and bacterial lipopolysaccharide (LPS), the latter being used as an adjuvant to potentiate the immune response. Once activated, these macrophages, dubbed M1 or M1-like, can function to acquire and present antigens to T_H cells and to effect tumor-cell killing by antibody-dependent cellular phagocytosis (ADCP) and antibody-dependent cellular cytotoxicity (ADCC; *left*). Acting in the opposite direction, hypoxia and a variety of tumor-derived signals direct the activation and differentiation of macrophages into the M2 phenotype, which causes them to foster rather than antagonize tumor formation (*right*); especially important among these M2 functions are those that create immunosuppressive tumor microenvironments. (A and B, from P. Martin et al., *Curr. Biol.* 13:1122–1128, 2003. With permission from Elsevier. C, from A. Fiumara et al., *J. Clin. Endocrinol. Metab.* 82:1615–1620, 1997. With permission from Oxford University Press. D, from L. Bingle, N.J. Brown and C.E. Lewis, *J. Pathol.* 196:254–265, 2002. With permission from John Wiley & Sons.)

As an example, T cells are often important regulators of the direction and degree of macrophage polarization. Members of the T_H1 subset of helper T cells (see Sidebar 15.3) and CTLs secrete interferon-γ, a cytokine that favors M1-like behavior, including phagocytic behavior and the generation of oxidizing agents, such as nitric oxide, that macrophages deploy to kill targeted cells. In contrast, other cytokines,

specifically the IL-4 and IL-13 secreted by another set of helper T cells termed T_H2 cells, can drive macrophages toward tumor-promoting M2-like phenotypes.

As multi-step tumor progression proceeds, at least during the formation of common, well-studied carcinomas, cancer cells begin to release immunosuppressive cytokines, the most prominent of which is TGF-β. This cytokine, on its own, exerts direct immunosuppressive effects by inducing the formation of M2 macrophages as well as the formation of an immunosuppressive subset of lymphocytes termed regulatory T cells (T_{reg}'s; to be described in Section 15.11).

Macrophages can attack and eliminate cancer cells simply by consuming them through the process of phagocytosis (see Figure 15.14C). Some cancer cells, however, having attracted the attentions of innate immune cells such as macrophages, may contrive a strategy for eluding macrophage-dealt phagocytic death; they do so by exaggerating an interesting aspect of normal tissue physiology. In order to protect themselves against inadvertent phagocytosis by roving macrophages, normal cells throughout the body display the CD47 protein—a "don't-eat-me" signal—on their surface. The CD47 receptor is one of several known receptors employed by normal cells throughout the body, including erythrocytes, to avoid inadvertent macrophage attack. CD47 levels are also used to determine the lifetimes of specific cell types in the body. For example, recently formed erythrocytes display high levels of CD47 that decline progressively in such cells until they approach the end of their pre-ordained lifetimes; at this stage CD47 has lost its ability to stave off attack by macrophages and closely allied immune cells, resulting in the removal of the aged red cells via phagocytosis.

Not surprisingly, many types of cancer cells up-regulate display of their CD47 don't-eat-me signal on their surfaces, thereby discouraging would-be macrophage attackers and overriding any tendency of macrophages to kill them via phagocytosis. Indeed, clinical observations have shown that circulating cancer cells, often referred to as circulating tumor cells (CTCs), released from certain human breast carcinomas display high levels of CD47, presumably offering protection against macrophages that are present in the circulation.

Once internalized by phagocytosis, ingested materials such as cancer cells are transferred to the lysosomes where they are enzymatically degraded. Phagocytosis can be facilitated if a potential target cell is coated by antibodies attached to cell surface molecules displayed by the target cell, much like the ADCC that is executed by NK cells (Section 15.9 and Sidebar 15.6). Phagocytic killing of target cells by this antibody-assisted route is called antibody-dependent cellular phagocytosis (ADCP). Like NK cells that carry out ADCC, macrophages display Fc receptors that, when engaged by antibodies bound to cell surface antigens, enable macraphages to kill the antibody targeted cells.

In fact, antibodies directed against tumor-associated cell surface antigens are employed by a variety of anti-cancer immunotherapies but do not seem to play major roles in the natural control and elimination of cancers. This explains why macrophage-mediated ADCP and NK-mediated ADCC are unlikely to be major factors in determining the clinical progression of most cancers. However, in the context of clinical settings, where monoclonal antibodies (MoAbs) targeting cancer cells are employed as therapeutic agents to kill cancer cells, both ADCP and ADCC can indeed be important contributors to the elimination of cancer cells. Examples of these antibody therapies will be presented in the next chapter.

Following the early stages of tumor development, a period when M1-like macrophages may contribute to cancer cell death, tumor-associated macrophage (TAM) populations progressively shift their phenotypes in ways that are more supportive of further tumor outgrowth, that is, increasingly transitioning from an M1 into an M2-like state. This seems to explain why clinical observations have shown that extensive macrophage infiltration of a clinically detectable tumor is generally an indicator of the presence of M2 macrophages and poor clinical prognosis. As an example, one meta-analysis of 55 studies of human cancers showed that dense infiltration of macrophages within a tumor mass correlated with poor overall survival in a wide variety of solid tumors, including breast, bladder, thyroid, and ovarian carcinomas. Images of macrophages presented in Figure 15.14 illustrate some of the many roles played by this class of versatile cells.

Glossary

alternatively activated macrophages
: A subtype of macrophages that releases immunosuppressive cytokines, notably IL-10 and TGF-β, and also favors tissue repair and regeneration. **Also called M2 macrophage**.

regulatory T cells
: A subset of CD4 lymphocytes that releases various immunosuppressive signals. *Also termed* **T_{reg} 's**.

tumor-associated macrophage
: A macrophage that has been recruited into a tumor.

M1 macrophage
: A subtype of macrophages that is associated with highly cytotoxic and phagocytic powers and can function to assist the immune attack on cancer cells. *Compare* **M2 macrophage**.

M2 macrophage
: A subtype of macrophages that releases immunosuppressive cytokines, notably IL-10 and TGF-β, and also favors tissue repair and regeneration. *Compare* **M1 macrophage**.

15.11 Regulatory T cells are indispensable negative regulators of the immune response that are co-opted by tumors to counteract immune attack

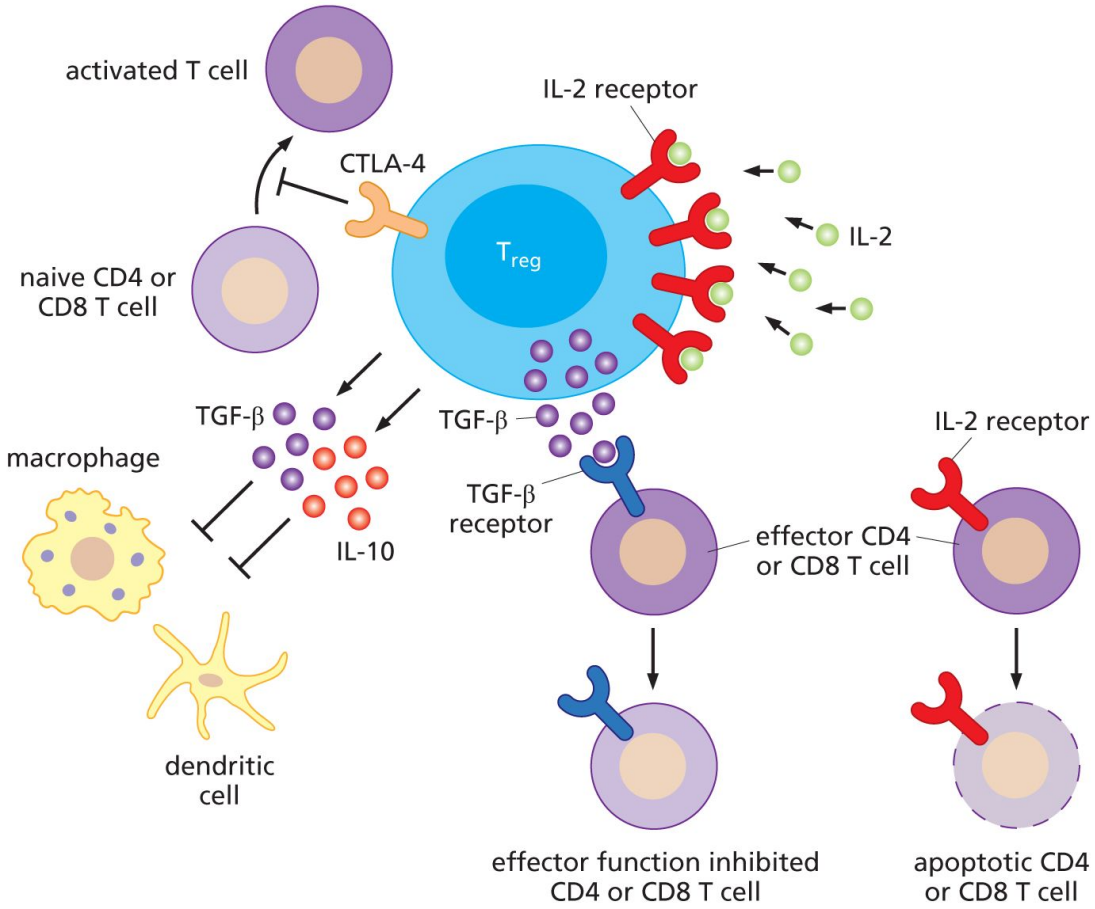
In contrast to the contributions made by most T-cell types to the elimination of cancer cells, one subtype of CD4 T cell, termed regulatory T cells (T_{reg}'s), actively aid tumor maintenance and progression, doing so by inhibiting various kinds of adaptive anti-tumor immune responses. More generally, T_{reg}'s play key immunoregulatory roles that are critical to the maintenance of normal tissue homeostasis. They do so by eliminating or suppressing autoreactive T cells, thereby playing a key role in ensuring immune tolerance. This particular function of T_{reg}'s is illustrated by studies using genetically altered mice that lack T_{reg} cells; such mice are afflicted by a lethal autoimmune disease that develops early in life. Similarly, humans who are unable for one reason or another to form T_{reg}'s develop an aggressive and ultimately fatal autoimmune disease.

Like the negative-feedback loops that modulate proper levels of mitogenic signaling in cells (as described in Section 6.14), the adaptive immune system requires counterbalancing inhibitory control mechanisms to constrain its actions. In the context of cancer development, T_{reg}'s can compromise the ability of the immune system to restrain tumor progression or eliminate tumor cell populations. We now know that they do so by inhibiting the effector functions and the proliferation of helper T cells and of CTLs. In addition, the actions of T_{reg}'s extend beyond their effects on T cells. Thus, they can inhibit effective antigen presentation by dendritic cells (see Section 15.7) as well as suppressing the anti-tumor activities of macrophages (see Section 15.10).

The formation of T_{reg}'s is strongly encouraged by TGF-β, which can induce their differentiation from CD4 lymphocyte precursors. Such differentiation can be monitored by the acquired expression of yet another cell surface marker protein, termed CD25. This induction of the T_{reg} state becomes important in the context of tumor pathogenesis because many types of transformed cells, including more mesenchymal carcinoma cells (see Section 13.3), actively secrete TGF-β, which can

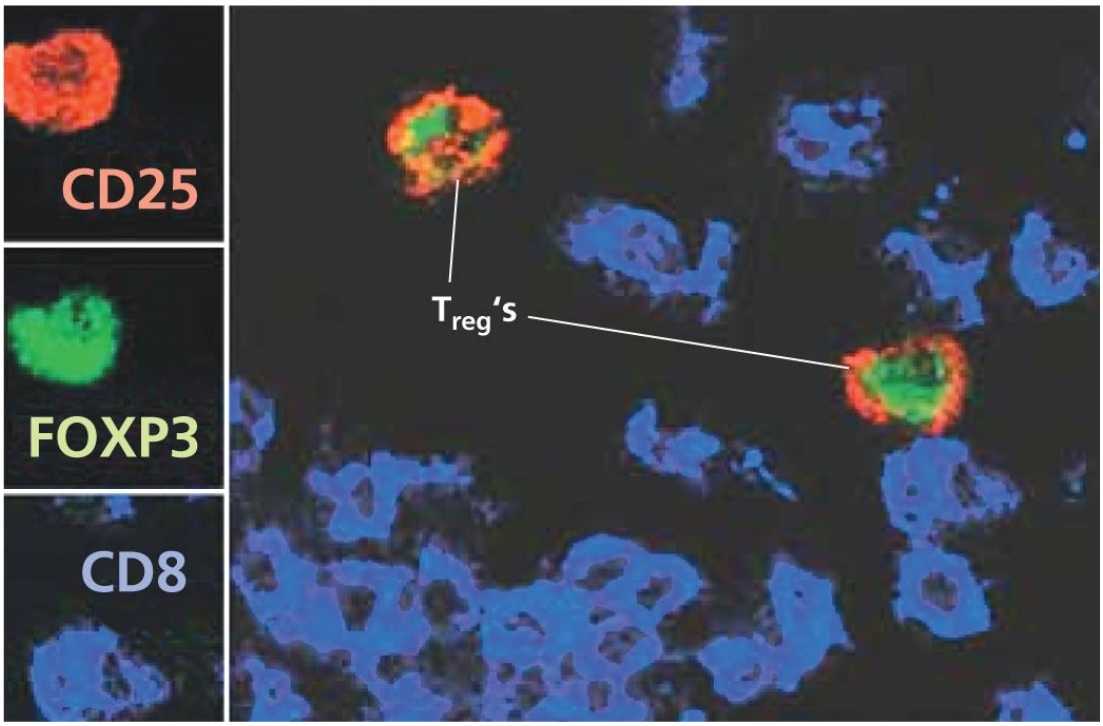
proceed to encourage the formation of more immunosuppressive, pro-tumor tissue microenvironments.

T_{reg}'s often constitute a significant proportion of the tumor-infiltrating lymphocytes (TILs) in lung, ovarian, breast, and pancreatic carcinomas as well as the immunocytes present in tumor ascites—the fluid accumulated in the peritoneal cavities of patients with several types of advanced cancers. Many tumors actively recruit T_{reg} cells to their associated microenvironments by releasing the chemokine CCL22. Regulatory T cells display a receptor for CCL22 and can sense CCL22 in their surroundings and advance toward the tumor cells that are generating the CCL22, doing so by following gradients of increasing concentration of this chemokine. Thus, this chemokine serves as a chemoattractant for these cells. These various aspects of T_{reg}-mediated immunosuppression are summarized in **Figure 15.15**.



A regulatory T cell engaged in multiple actions. With a C T L A-4 receptor on its surface, it inhibits the conversion of a naive C D 4 or C D 8 T cell into an activated T cell. On another part of the regulatory T cell's surface, multiple interleukin 2 receptors bind free-floating interleukin 2 molecules. This causes

interleukin 2 receptors on effector C D 4 or C D 8 T cells to remain empty, causing those cells to become apoptotic. The regulatory T cell also secretes transforming growth factor beta, which binds to T G F beta receptors on effector C D 4 or C D 8 T cells, causing their effector function to be inhibited. Finally, the regulatory T cell secretes interleukin 10, which together with T G F beta reduces the activity of dendritic cells and macrophages.
(A)



A fluorescence microscopy image showing colored cell nuclei against a black background. Most nuclei are dark blue, indicating the presence of C D 8. Two, however, have green centers and red edges. The green is a marker for FOX P3. The red is a marker for C D 25.

(B)

Figure 15.15 Regulatory T cells (A) Regulatory T (T_{reg}) cells act on other immunocytes in multiple ways. The CTLA-4 receptor has a higher affinity for the co-stimulatory ligands CD80/86 than does CD28 on other T cells. Consequently, CTLA-4 can bind to these co-stimulatory ligands and inhibit the activation of naive T cells to functional effector T cells by preventing them from receiving the co-stimulation on which their priming depends (*above left*). Interleukin-2 (IL-2) is an essential factor for the survival and proliferation of effector T cells. T_{reg}'s display high densities of the IL-2 receptor (IL-2R) on their surface, allowing them to bind and sequester IL-2, thereby denying the essential support by IL-2 to other

T cells in their vicinity (*above right*). TGF-β secreted by T_{reg} cells can inhibit the activity of multiple types of effector T cells, including subsets of CD4 helper T cells, as well as CTLs. T_{reg}'s also secrete IL-10, a potent inhibitory cytokine that collaborates with TGF-β in reducing the activity of dendritic cells and macrophages (*lower left*). By inhibiting helper T cells with secreted cytokines like TGF-β, these T_{reg} cells can reduce antibody production by B cells (*middle left*). By depriving CD4 and CD8 T cells of IL-2 (*middle right*), T_{reg} cells can also trigger apoptosis of CD4 and CD8 cells. (B) Immunofluorescence staining reveals the presence of T_{reg}'s through their expression of the CD25 surface antigen (*red*) and the FOXP3 transcription factor (*green*), which is localized to the nuclei of these cells. They are seen here amid CD8+ cytotoxic T cells (*blue*), whose actions they are ostensibly inhibiting; these lymphocytes were present in the ascites of a patient suffering from ovarian cancer. (A, adapted from X. Meng, et al., *Nat. Rev. Cardiol.* 13:167–179, 2016. B, adapted from E.M. Shevach, *Nat. Med.* 10:900–901, 2004. With permission from Nature.)

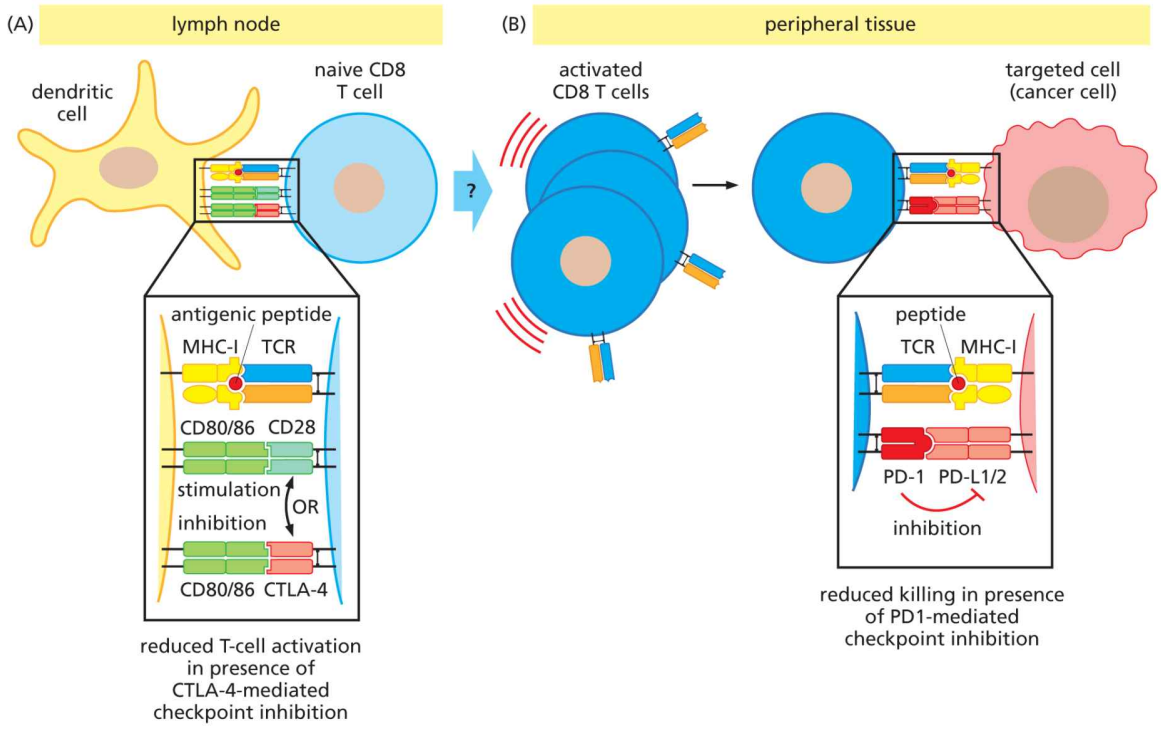
15.12 Immune checkpoints act to limit immune responses

Once set in motion, immune responses can pose threats to the normal host tissues comparable to those created by infectious pathogens or tumor cells. An elaborate set of controls, including the T_{reg}'s just described, ensures that these responses are limited and eventually shut down once immune responses have completed their work. Moreover, as argued repeatedly above, over extended periods of time, organismic survival depends on mechanisms of immune tolerance to spare normal tissues from immune attack.

In contrast with the receptor–ligand interactions that promote immune responses, those underlying the operations of immune checkpoints dampen immune responses and ensure that they are self-limiting. These checkpoints depend on *juxtacrine* receptor–ligand interactions involving cell–cell contact (see Figure 5.8), which negatively regulate immune responses and, in this respect, contrast with the influences of soluble *paracrine* immunosuppressive cytokines and the T_{reg}'s described in Section 15.11. We now turn to an exploration of this juxtacrine signaling because it is essential to understanding how cancers develop in the face of existing immunological surveillance and how already developed cancers acquire the ability to elude anti-cancer immunotherapies directed against them.

To begin, we return to the interactions between DCs and their potential T-cell partners. Thus, as antigen-presenting dendritic cells physically approach potential T-cell partners within lymphoid tissues, they display on their surface the CD80 and CD86 "co-stimulatory ligands" either of which can engage with CD28, a stimulatory co-receptor on the surface of T cells distinct from their TCRs. Hence, in addition to recognition of peptide:MHC-I complexes by TCRs, effective T-cell responses are promoted by and dependent on an additional essential co-stimulatory interaction mediated by this co-receptor, which enables the conversion of naive T cells into the activated lymphocytes that participate thereafter in immune responses. In fact, naive T cells staunchly resist activation simply by engagement of their TCR signaling, whereas the powerful combination of stimulation by peptide:MHC (acting on the TCR) plus co-stimulation by CD80/86 (acting on CD28) is sufficient to push normally activation-resistant naive T cells into a state of activation.

The actions of these co-stimulatory interactions are counterbalanced by certain immune checkpoint mechanisms, which include co-inhibitory receptor–ligand interactions that limit the *intensity* of T-cell activation during the initial induction of immune response described above (**Figure 15.16**).



A two-part figure depicting regulation of the activation and effector phases of T-cell response. Part A, titled reduced T-cell activation in presence of C T L A-4-mediated checkpoint inhibition, shows the activation phase unfolding in the lymph node, as a dendritic cell makes contact with a naive C D 8 T cell. Activation is achieved through the coupling of a peptide M H C 1 complex on the dendritic cell with a cognate receptor on the T cell. Also presented on the surface of the dendritic cell is a C D 80 slash 86. If this binds to a C D 28 on the T cell, activation is stimulated, whereas if the C D 80 slash 86 binds to a C T L A-4 on the T cell, activation is inhibited. Part B, titled reduced killing in presence of P D1-mediated checkpoint inhibition, shows the effector phase unfolding in peripheral tissue, as an activated dendritic C D 8 T cell makes contact with a target cell, which is a cancer cell. An attack by the T cell is triggered when a T cell receptor couples with a cognate peptide M H C 1 complex on the target cell. This triggering is inhibited if a P D-1 on the T cell binds with a P D-L1 slash 2 on the target cell.

Figure 15.16 Checkpoint inhibition of T-cell activation and effector function Checkpoint controls ensure the limiting or shutdown of the T-cell response and operate in two successive phases of response development. (A) Activation phase. A naive T cell is primed within a lymph node by engagement of its TCRs with cognate peptide:MHC-I complexes presented by a dendritic cell (DC) (*left*). The essential co-stimulation that is necessary to augment signaling from the TCR into the T cell is provided by engagement of the T cell's co-stimulatory receptor, CD28, with stimulatory ligands (CD80/86) displayed on the surface of the dendritic cell (*inset, above*). The combined strength of these signals is sufficient to force activation of the naive T cell, causing it to undergo proliferation and develop effector functions. An alternative counteracting response occurs when the CTLA-4 receptor of a T cell, rather than its CD28 receptor, binds to CD80/86 of a dendritic cell: rather than stimulating the T cell and causing its activation, this CTLA-4:CD80/86 binding generates signals that inhibit T-cell activation (*inset, below*). CTLA-4 binding to the CD80/86 ligands is stronger than is CD28 binding; hence, the inhibitory effects of CTLA-4 dominate if both are expressed. As the activation of T cells mediated by CD28 proceeds, the levels of CTLA-4 increase progressively, ultimately ensuring the shutdown of further CD28 signaling and resulting T-cell activation. Those T cells that undergo successful activation leave the lymph node via the circulatory system and are carried to peripheral tissues. This negative-feedback control of T-cell activation operates independently of the T_{reg} inhibition described in Figure 15.15. (B) Effector phase. Those CD8 T cells that are successfully activated by antigen exposure (*broad blue arrow*) are exported from the lymph node and disperse into peripheral tissues, in this case a tumor (*right*). There they enter the tumor microenvironment (TME), where recognition of peptide:MHC complexes displayed by cancer cells can provoke a cytotoxic attack by the activated CD8 T cells. However, the presence of PD-1, an inhibitory receptor also displayed on the surface of the cytotoxic CD8 cells, renders them susceptible to inhibition if they happen to encounter the inhibitory ligands PD-L1 or PD-L2 (PD-L1/2) displayed either by cancer cells or by other noncancerous bystander cells present in the TME (*inset*). (Adapted from R.J. Lee, J.S. Abramson and R.A. Goldsby, Case Studies in Cancer. New York: W. W. Norton & Company, Inc., 2018.)

This initial activation of a T-cell in a lymphoid tissue is limited by a counterbalancing inhibition mediated by the CTLA-4 T-cell co-inhibitory receptor, this action representing an initial critical checkpoint control occurring

within the lymphoid tissue. As Figure 15.16 indicates, CTLA-4 is activated by its cognate CD80/86 ligand displayed by the dendritic cell and proceeds thereafter to damp down T-cell activation. Hence, the CD80/86 proteins displayed by DCs serve as ligands for two mutually antagonistic receptors, one stimulatory, the other inhibitory (**Sidebar 15.7**).

Sidebar 15.7 Checkpoint controls reflect the operations of conflicting regulatory molecules

A variety of counter-balancing receptor–ligand interactions operate together to form an elaborate network of cell–cell signaling dedicated to stimulating or suppressing immune attacks on various normal cells throughout the body. To review, this sequence of interactions begins with naive CD8+ T cells in lymphoid tissue, where the CD28 receptor acts as a co-receptor with the TCR also displayed by the CD8+ T cell; when the CD8+ T cell's TCR recognizes a peptide antigen displayed by a dendritic cell (DC), the presence of CD80/86 molecules on the DC surface engages the CD28 receptor displayed by the CD8+ T cell, generating a combined signal strong enough to activate or "prime" it and, in principle, enable it to function thereafter as a CD8+ cytotoxic T lymphocyte (CTL) capable of subsequent action elsewhere in the body. For this reason, CD28 is often termed a co-stimulatory receptor, acting in partnership with the TCR.

The CTLA-4 receptor is also displayed by a CD8+ T cell encountering antigen within lymphoid tissue. This receptor also recognizes and binds CD80/86 displayed by a dendritic cell. This last fact places the two co-receptors displayed by T cells—CD28 and CTLA-4—in conflict and in direct competition with one another for binding their common ligands CD80/86 displayed by DCs. Initially, the stimulatory effects of the CD28:CD80/86 association may dominate and result in successful activation of the T cell, but as this interaction proceeds, increasing levels of the CTLA-4 co-inhibitory receptor are now displayed on the surface of the T cell. Because CTLA-4 binds the critical CD80/86 ligands (on the DC) more avidly than does CD28, it eventually prevails, displacing CD28 binding and shutting down further stimulation of the T cell. Hence, CTLA-4 functions to mediate as a negative feedback control that is only imposed with some delay after T cell:DC interaction.

The physiological importance of the CTLA-4 inhibitory receptor is illustrated most dramatically by the consequences of its deletion from the control circuitry of

the immune response. Studies in mice demonstrate that germ-line deletion of *ctla4*, the gene encoding CTLA-4, results in massive lymphoproliferative disease that kills such animals within 3 to 4 weeks after birth; this demonstrates the key role of the CTLA-4 response in constraining T-cell *proliferation* following an initial encounter with activating antigens.

Later, when the now-activated T cell leaves a lymphoid tissue and disperses to tissues throughout the body, the T cell's inhibitory PD-1 co-receptor comes into play. Thus, if and when the TCR of this CTL recognizes cognate antigens displayed by these target cells, this T cell will launch an attack on the latter. Only then does the T cell's PD-1 co-receptor confront its PD-L1/2 ligands displayed by the target cells in one or another peripheral tissue. Thus, the juxtracrine PD-1:PD-L1/2 interaction will eventually intervene to curtail further T-cell activity. This shutdown of further CTL-mediated attack may also occur, for example, upon protracted antigen stimulation or exposure to certain inflammatory conditions.

These two sets of interactions—CTLA-4 with CD80/86 in lymphoid tissues and PD-1 with PD-L1/2—represent the signaling agents controlling the two successive immune checkpoint mechanisms that have been most thoroughly studied to date, and both underlie now well-established cancer immunotherapies as we will read in the next chapter.

In the presence of a sufficiently high level of PD-1 ligands, persistent antigen stimulation in a peripheral tissue may drive a T cell into a state of T-cell exhaustion. Exhausted T cells typically display high levels of PD-1, together with other inhibitory checkpoint receptors, and at the same time exhibit significantly reduced functional capacity. However, despite the implications of the term "exhausted," such T cells have not lost all functional capacity and may still contribute to T-cell responses, including anti-tumor responses, albeit at greatly reduced levels.

To summarize, the two checkpoint controls, involving the CTLA-4 and PD-1 co-receptors operating one after the other, exert a moderating influence that is necessary to (1) avoid excessive, acute immune responses, (2) discourage the development of autoimmunity and, as a consequence, (3) prevent or limit the tissue damage and systemic pathology that can result from prolonged or chronic T-cell activation and accompanying chronic inflammation.

OceanofPDF.com

Glossary

immune checkpoint
: Control mechanism ensuring that immune attacks on cells and tissues are constrained or limited, achieved by modulating downstream signaling responses such as those triggered by receptor–ligand interactions between immunocytes and target cells. *See also* **checkpoint**.

co-inhibitory
: (1) Referring to a molecule or process that operates in concert with a major inhibitory process to ensure completion of the latter or to amplify its effects. (2) Receptor that, when displayed in conjunction with a T-cell receptor, will dampen the duration of subsequent T-cell activation; such a receptor will recognize a ligand presented by a potential target cell. *See also* **co-stimulatory**.

co-stimulatory
: (1) Referring to molecules or processes that operate in concert with a major stimulatory process to ensure completion of the latter or to amplify its effects. (2) Referring to a receptor that, when acting in concert with a T-cell receptor, can act to stimulate the resulting T-cell response; such a receptor will recognize a ligand displayed by a potential target cell. *See also* **co-inhibitory**.

T-cell exhaustion
: State of a T cell that has been induced by prolonged, possibly excessive antigen exposure as well as by exposure to certain cytokines, and is associated with loss of its various effector functions.

15.13 Synopsis and prospects

Once formed, cancer cells confront the immune system as a major threat to their ongoing survival and progression to states of high-grade malignancy. Indeed, most cancer cells and the tiny incipient tumors that they form may be eliminated entirely by the immune system, leaving no record of their formation; hence, the tumors that are registered clinically may only represent a minute proportion of those that are initially formed. Alternatively, early-stage tumors may be held in check by the adaptive immune system and limited to forming small indolent growths that may never become clinically manifest. The cells in such tumors may continue to proliferate slowly, with immunogenic subpopulations being continually eliminated by CTLs and by other cytotoxic immune cells. These mechanisms, to the extent that they operate, effectively preclude us from gauging precisely how effective the immune system truly is in protecting us against cancer.

Nonetheless, macroscopic tumors do erupt, underscoring why avoidance of immune destruction is considered a fundamental hallmark of cancer (see Section 11.3). Eventually, an initial delicate balance between survival and immune destruction may be disrupted, tipping away from susceptibility to immune attack and toward expansion of the tumor cell population. Ironically, the powerful selective force exerted by the immune system that is designed to eliminate cancer cells can provide a mechanism that promotes the evolution of cancer cell populations that are resistant to immune attack.

Tumor cell populations are heterogeneous and some cells within individual tumors have antigenic profiles that make them more immunogenic than others. One consequence of the operation of immune selection is likely to be the elimination from populations of heterogeneous, early-stage tumor cells of the more immunogenic variant cells, leaving behind populations that may be more capable of resisting immune attack, in part via some of the mechanisms described in this chapter.

The selective processes that favor the emergence of less immunogenic cancer cells have been termed immunoediting. Immunoediting represents a form of Darwinian selection in which fitness is determined by absence of effective antigenicity while the adaptive immune system works as the selective force. One inevitable consequence often follows: over extended periods of time, immunoediting can result in the evolution and eventual outgrowth of tumor cell populations against which the immune system is powerless.

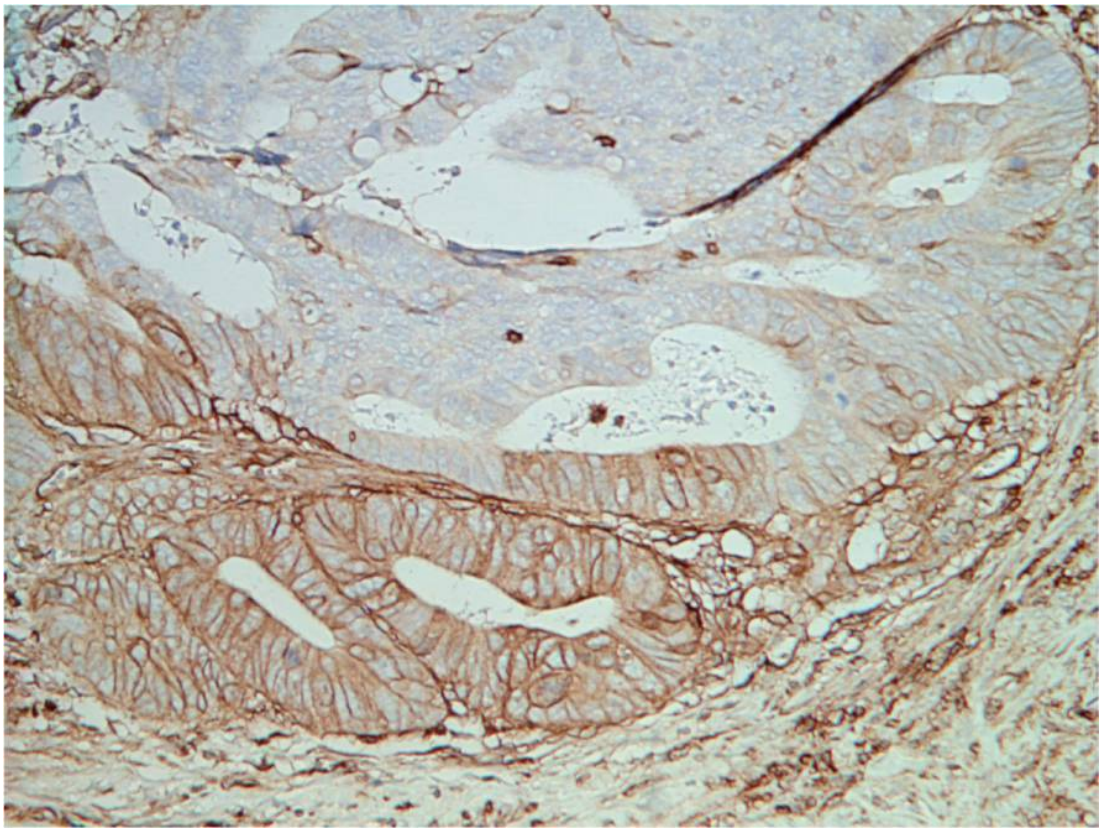
The most obvious strategy mounted by tumor cells to avoid such selection via immunoediting involves shutdown of the expression of immunogenic antigens. In fact, tumors often harbor cell clones that have entirely lost expression of certain tumor antigen-encoding genes as a consequence of DNA methylation of the promoter regions of these genes (see Section 7.7) or outright deletion of the encoding chromosomal DNA sequences. Many of the tumor antigens affected by these types of cancer cell-intrinsic immunoevasive maneuvers derive from proteins whose continued expression is not critical to continued cancer cell viability and proliferation. (Such proteins are often, for example, the products of mutant passenger gene alleles.)

In many cases, however, cancer cells cannot simply resort to down-regulation of the expression of an immunogenic tumor antigen if its continued functions are essential for cellular function or neoplastic proliferation. For example, the overexpressed but otherwise-normal HER2/Neu protein—a growth factor receptor displayed by more than 20% of human breast cancers—may provoke an anti-tumor immune attack (see Figure 4.3). In this case, however, the neoplastic cells in these breast carcinomas *depend* on continued expression and functioning of this receptor protein to drive their proliferation and avoid apoptosis, and for this reason, they simply cannot afford to shed this critical tumor antigen. One response by a cancer cell unable to down-regulate expression of a key tumor antigen might involve the remodeling of this antigen through changes in its primary amino acid sequence that erase an antigenic determinant; this maneuver often does not represent a viable solution, given the potentially disruptive effects of many structural changes on the continued functioning of an essential cancer-forming protein.

Yet another alternative immunoevasive strategy may derive from reducing or halting the cell surface presentation of a targeted tumor peptide antigen by MHC-I proteins. This approach avoids attack by cytotoxic T cells (CTLs) whose TCRs specifically recognize the peptide:MHC-I complexes formed by such an antigen. This strategy can be executed by either a shutdown of MHC class I protein expression or a failure to properly load peptides onto the MHC-I carrier molecules during their maturation in the endoplasmic reticulum. There is evidence that both these evasive maneuvers are employed.

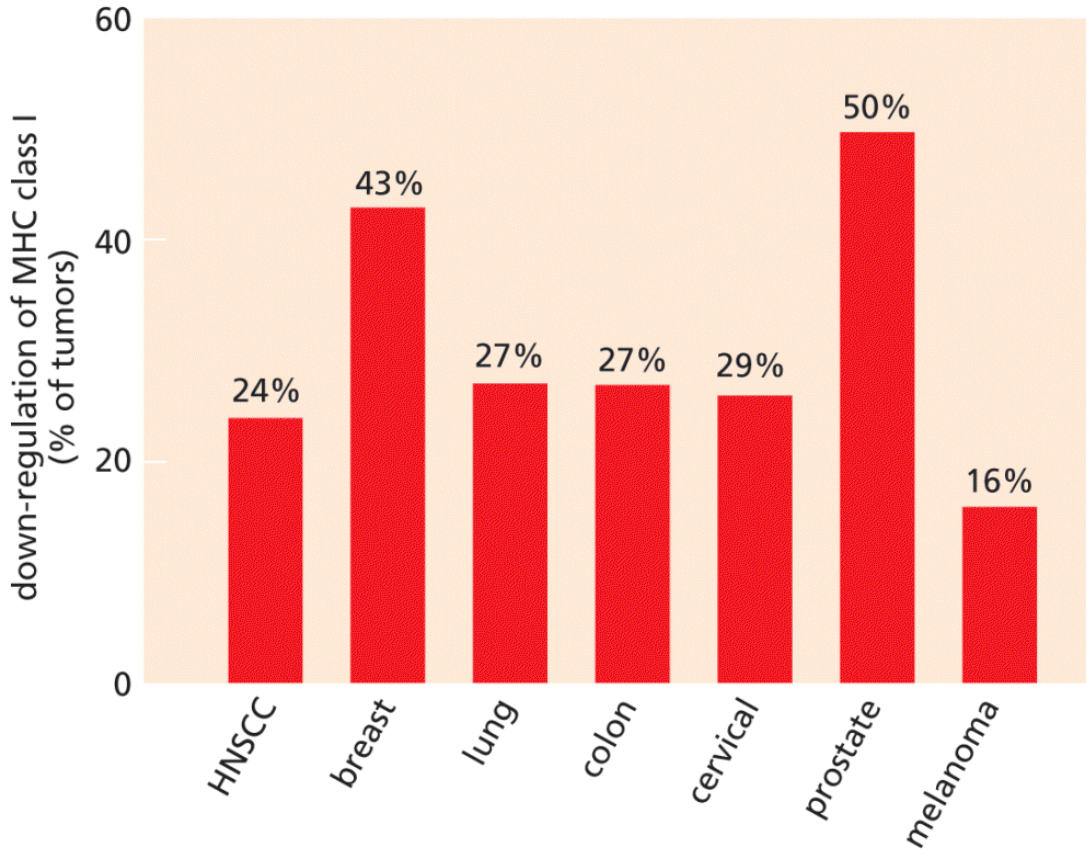
Suppression of MHC class I protein expression is often achieved through transcriptional repression of their encoding genes. In fact, many types of human cancer cells have been found to lack normal levels of the mRNAs encoding these MHC molecules, thereby preventing their synthesis and thus display of antigens at the cell surface (**Figure 15.17**). Alternatively, cancer cells can also use post-translational mechanisms to reduce MHC class I-mediated antigen presentation. For instance, the migration of MHC molecules from the endoplasmic reticulum to the cell surface depends on their association with β_2-microglobulin protein (β_2m). Normally, β_2m escorts the MHC molecules and their peptide cargo to the cell surface (**Figure**

15.18A). In certain high-grade tumors, however, the absence of β_2m synthesis prevents the peptide-loaded MHC class I molecules from reaching the cell surface (Figure 15.18B).



A histology stain image. The lower part, in which several ducts are visible in cross section, is a pale orange or pink, while the upper part, in which no ducts are visible, is a neutral gray.

(A)

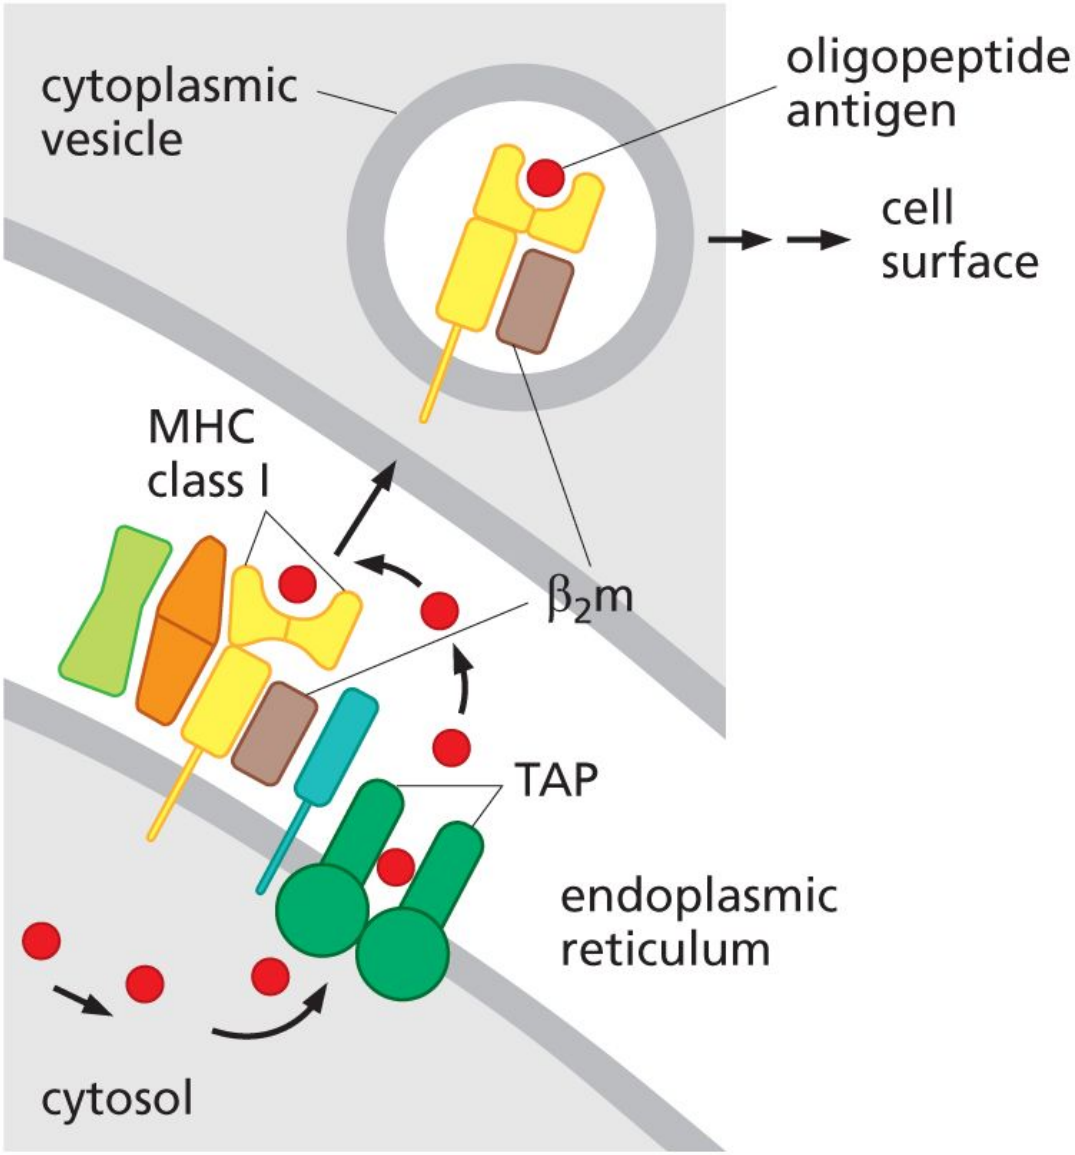


A bar graph showing what percent of tumors display down-regulation of M H C class 1. The percentages range from 16 percent for melanoma to 50 percent for prostate cancer. In between those extremes are Head and neck squamous cell carcinoma, at 24 percent; breast cancer, at 43 percent; lung cancer and colon cancer, each at 27 percent; and cervical cancer, at 29 percent.

(B)

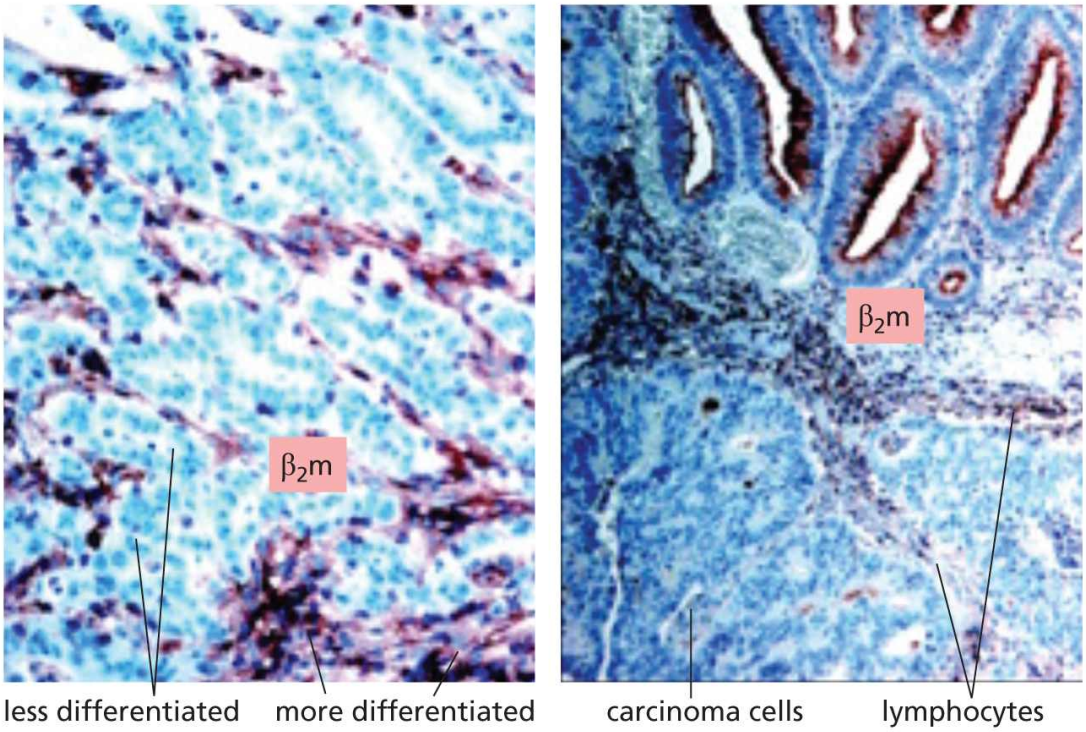
Figure 15.17 Immunoevasion through suppression of MHC class I expression
Cancer cells will often down-regulate expression of their MHC class I molecules, ostensibly in order to avoid recognition and attack by cellular components of the adaptive immune response. (A) Shown here are cells of a human colorectal tumor that have been immunostained with an antibody that recognizes a specific subtype of human MHC class I molecule termed HLA-A. The carcinoma cells in the lower part of the tumor strongly express HLA-A (*dark red*), whereas the cells in the upper part of the tumor have partially or totally shut down HLA-A expression. (B) Shown on the ordinate is the percentage of tumor samples in which down-regulation of MHC class I expression occurred in a significant segment of the tumors examined (HNSCC, head-and-neck squamous cell carcinoma.) (A, from

A.G. Menon et al., *Lab. Invest.* 82:1725–1733, 2002. With permission from Nature. B, courtesy of S. Ferrone.)



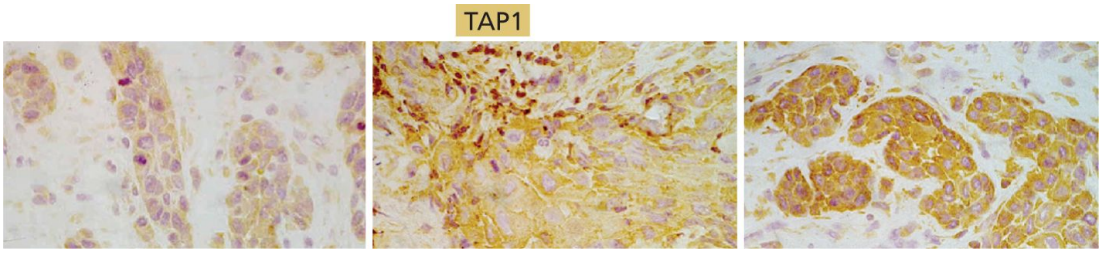
A diagram of a process that begins in the endoplasmic reticulum of a cell. An oligopeptide antigen is funneled from the cytosol into the endoplasmic reticulum by a pair of T A P proteins. From there, the oligopeptide comes to rest on the receptor end of an M H C 1 complex. At the same time, a beta 2 m molecule binds to the underside of the M H C 1 complex. The oligopeptide M H C 1 beta 2 m complex is sequestered into a cytoplasmic vesicle that delivers the complex to the cell surface.

(A)



Two histology stain images. In the left one, less differentiated tissue appears as large areas of cyan, and more differentiated tissue appears as veins of dark purple with reddish brown spots that indicate the presence of beta 2 m. In the right image, carcinoma cells appear as large areas of cyan, and lymphocytes appear as veins of dark blue with reddish brown spots that indicate the presence of beta 2 m.

(B)



A sequence of three histology stain images. In the left one, the tissue appears pink. In the middle image, the tissue appears yellowish tan. In the right image, the tissue appears pink with islands of yellowish tan.

(C)

Figure 15.18 Failure of antigen presentation from loss of TAP1 orβ_2-microglobulin (A) The TAP complex is a heterodimer of the TAP1 and TAP2 proteins (transporters associated with antigen processing; *dark green*) that is involved in transporting oligopeptides (*red dots*) from the cytosol into the lumen of the endoplasmic reticulum, where the oligopeptides can be loaded onto MHC class I molecules (*yellow*). Independent of this, the β_2-microglobulin (β_2m, *light brown*) molecule associates with MHC class I molecules and helps to shepherd them, together with their captured oligopeptide antigens, to the cell surface. The MHC class I molecules require both a bound oligopeptide antigen and an associated β_2m molecule in order to reach the cell surface via cytoplasmic vesicles (*above*). Hence, defects in either the β_2m or TAP protein expression can preclude MHC-I-mediated presentation of oligopeptide antigens on the cell surface. (B) In one human colorectal carcinoma (*left panel*), β_2m staining (*reddish brown*) is present in the cancer cells forming the more differentiated tubular structures (*below*), while the less differentiated carcinoma cells (*light blue, above*) fail to express any β_2m. In a second colorectal carcinoma (*right panel*), β_2m is present in infiltrating lymphocytes (*dark red*) but is totally absent in many of the carcinoma cells (*light blue, bottom half*). In 5 of 17 microsatellite-unstable (MIN) colorectal tumors (see Section 12.3), the β_2*m* gene was found to have suffered inactivating mutations and was transcriptionally silenced through unknown mechanisms in a number of other tumors. (C) Defective antigen processing is frequently seen in head-and-neck squamous cell carcinomas (HNSCCs), in which expression of TAP1 or TAP2 is often lost. The immunohistochemical staining shown here reveals the expression of TAP1 (*beige*) in a group of HNSCCs to be variable, being absent in some tumors (*left*), present in patches in others (*middle*), and normally expressed in yet others (*right*). (A, from C.A. Janeway Jr. et al., Immunobiology, 6th ed. New York: Garland Science, 2005. B, from M. Kloor et al., *Cancer Res.* 65:6418–6424, 2005. With permission from American Association for Cancer Research. C, courtesy of Barbara Seliger.)

An even earlier step in antigen presentation may also be compromised: some tumors have defective TAP1 or TAP2 (*t*ransporter associated with *a*ntigen *p*resentation) proteins (see Figure 15.18A). These proteins are essential for the transport of peptides generated by the proteasomes in the cytosol to the ectodomains of MHC class I molecules present in the lumen of the endoplasmic reticulum. Without help from both TAP proteins, antigen presentation by MHC molecules once again fails (Figure 15.18C).

These various attempts at immunoevasion can be countered, however, through dispatch by the immune system of NK cells, which are programmed to attack cells that

lack adequate levels of MHC class I protein expressed on their surface. The tumor, for its part, may respond in turn by launching a counter-counterattack, doing so by secreting TGF-β, which proceeds to shut down NK cells. The back and forth, cat-and-mouse games may continue for extended periods of time with ultimate outcomes that are hardly predictable.

Another defense against attacks launched by the immune system depends on cancer cells modifying the extended tumor microenvironments (TME) around them, using diffusible substances to weaken various types of immune attacks. Interleukin-10 (IL-10) and TGF-β are broadly immunosuppressive agents that are produced by some cancer cells and by certain types of immune cells present in the TME. They suppress T-cell proliferation and can inhibit antigen presentation by dendritic cells. Under appropriate conditions, TGF-β can induce the generation of the strongly immunosuppressive regulatory T cells and inhibit NK function, both being strategies cited earlier.

Carcinoma cells that have activated portions of the epithelial-mesenchymal transition (EMT) cell-biological program described in Chapters 13 and 14 often secrete significant amounts of TGF-β that they depend on, since it operates via an *autocrine* signaling mechanism to help these cells maintain their continued residence in more mesenchymal phenotypic states. However, this secreted TGF-β can also extend its reach further by acting in a *paracrine* manner to suppress a variety of immune cells that have ventured too close to islands of tumor cells. In the case of IL-10, study of the Epstein–Barr virus (EBV) genome (see Section 3.4) has revealed the presence of an IL-10-like viral gene of clear cellular origin that was acquired by the distant ancestors of the virus. In an earlier chapter, we read that this virus is an important etiologic agent of Burkitt's lymphomas, other lymphomas of the B-cell lineage, and nasopharyngeal carcinomas. It appears that EBV forces an infected cell to release an IL-10-like immunosuppressive cytokine, protecting this cell from attack by cytotoxic immune cells, which serves in turn to preserve the infected host cell in a viable state for an extended period of time while the virus exploits its continued viability to ensure viral proliferation and progeny virus formation.

Tumors host a broad variety of immunosuppressive cell populations. The repertoire of suppressive populations may include one or more of the following cell types: regulatory T cells, tumor-associated macrophages (TAMs), tumor-associated neutrophils (TANs), and myeloid-derived suppressor cell (MDSC) populations. Increased numbers of these immunocyte populations provide immunosuppressive environments that are hostile to immune control and elimination of tumor cells. In fact, a subset of B cells, known as regulatory B cells (B_{reg}'s) has recently come to light. Similar to their T_{reg} cousins, B_{reg}'s secrete the immunosuppressive cytokines IL-10 and TGF-β. They have also been found in the tumor microenvironment and are

associated with the suppression of immune responses. Further study will provide more indications of their impact on tumor maintenance and progression and of their utility as prognostic clinical indicators.

As an alternative strategy for immunoevasion, some cancer cells may alter their intracellular biochemistry in order to render themselves intrinsically less vulnerable to cytotoxic T cell attacks. For example, some cancer cells become resistant to being killed following an initial encounter with the FasL death receptor ligand wielded by cytotoxic T cells; they do so by altering their intracellular signaling pathways downstream of their Fas death receptor. This pathway dysregulation results in the inactivation of the extrinsic apoptotic pathway (see Figure 9.31), providing cancer cells with yet another way to escape death.

A related immunoevasive strategy reflects strategies used to escape the major mechanism employed by cytotoxic T cells and NK cells to kill their target cells. Thus, CTLs and NK cells introduce proteases—granzymes—into targeted cells to induce apoptosis through cleavage and the resulting activation of a caspase pro-enzyme involved in triggering this cell death program (see Figure 9.31). Cancer cells can escape this killing mechanism by increasing the levels of certain inhibitor-of-apoptosis proteins (IAPs; see Figure 9.27), which sequester and inactivate key pro-apoptotic caspases, thereby blunting any activation of the extrinsic apoptotic pathway.

To summarize, immune-initiated cytotoxicity can be viewed as yet another physiological stressor experienced by cancer cells during multiple stages of multi-step tumor progression, taking its place alongside hypoxia, intracellular signaling imbalances, and loss of anchorage, all of which force cancer cells to disable their pro-apoptotic signaling pathways. Although extensive and various, the list of immunoevasive strategies explored here should not be considered complete and is likely to be extended in various directions by future research.

The next chapter reveals powerful and still-developing immunotherapies designed to defeat or bypass many of the defenses erected by cancer cells to thwart or avoid immune attack. Like the targeted therapies explored in early chapters, the inspiration for these immunotherapies and the guidance for their development emerged from the increasing and still-developing understanding of basic immunology and cancer immunobiology described in this chapter.

Glossary

immunoediting
: Process in which the selective pressure imposed by immune surveillance and attack eliminates strongly immunogenic tumor cells while permitting the survival and outgrowth of those that are weakly immunogenic.

OceanofPDF.com

Key concepts

- Normally, the immune system displays tolerance, the failure to mount immune responses against self. Because tumor cells are very similar to their normal counterparts, tolerance can be a barrier that must be overcome in order to make an anti-tumor immune response against them.
- Immunocompromised individuals experience elevated levels of various cancers, strongly suggesting that the immune system is continuously monitoring the body's tissues for the presence of tumors and attempting to eliminate them—the process of immunosurveillance.
- There are two types of tumor antigens: tumor-specific antigens (TSA) and tumor-associated antigens (TAAs). Tumor-specific antigens are expressed by some or all of the cells of a given tumor. Tumor-associated antigens are expressed by tumor cells and certain other normal tissues throughout the body; they often reflect the differentiation programs of the tissues in which these tumor cells arose.
- In vertebrates, immunity is provided by the innate immune system and the adaptive immune system, two distinct, but interacting physiological systems. Innate immune responses are triggered by broadly specific pattern-recognition receptors. Adaptive immune responses are triggered by engagement of receptors that are highly specific for a given antigen.
- Two classes of lymphocytes, B lymphocytes (B cells) and T lymphocytes (T cells), are the signature cell types of adaptive immunity. Antibodies, their B-cell receptor counterparts, T-cell receptors and, in complexes with their peptide ligands, MHC-I and MHC-II molecules enable the adaptive immune system to recognize and respond to diverse antigens.
- The extensive diversity of antibodies and T-cell receptors is achieved by the stochastic rearrangement of a few hundred subgenic segments that are inherited in the germ line and can combine almost randomly during the development of B cells and T cells. The resulting molecules, assembled combinatorially, are enormously diverse and generate T cell

and B cell repertoires exceeding 10^9 potential antigen specificities in each individual human.

- The T-cell receptors (TCRs) of the body's major T-cell population do not recognize intact protein antigens but instead respond to complexes of peptide fragments derived from intracellular degradation of peptide fragments presented as complexes with MHC molecules.
- Somatic cells throughout the body routinely present peptide fragments of proteins synthesized within their confines as peptide:MHC class I on their surface. A very few cell types—macrophages, B cells, and most notably, dendritic cells—have the ability to present peptides derived from proteins acquired from outside their confines as complexes of peptide:MHC class II molecules.
- Whether T cells recognize MHC-I–bound or MHC-II–bound peptides is determined by a co-receptor protein, either CD4 or CD8, that is associated closely, but noncovalently, with TCRs on their surface. The co-receptors ensure that the TCR with which they are partnered is directed toward the appropriate MHC molecule. CD8 T cells interact with MHC class I molecules and CD4 T cells interact with MHC class II molecules.
- T cells that have not undergone an encounter with antigen that resulted in their activation are referred to as naive T cells. They are unresponsive, except under the special circumstances designated as priming. Conditions for priming are demanding and include antigenic stimulation, an additional signal called co-stimulation, and the presence of appropriate cytokines. During priming, naive T cells almost always receive antigenic stimulation and co-stimulation from dendritic cells.
- Dendritic cells are able to present peptides on both MHC-I and MHC-II molecules, a distinctive feature of their physiology called cross-presentation, which enables presentation to either naive CD4 or CD8 T cells. Their display of the co-stimulatory ligands, CD80/86, also allows dendritic cells to deliver co-stimulatory signals. Given the presence of appropriate cytokines, this combination of TCR and co-stimulatory signaling, effects the transformation of T cells from the naive state to the state of activation.
- Different functions are assumed by CD8 and CD4 T cells. Cytotoxicity is the function of CD8 T cells, and CD4 T cells are primarily involved

in the positive or negative regulation of other T cells and some other types of immunocytes. CD4 T cells that deliver signals supporting cell functions are referred to as helper T cells (T_H cells) and those that inhibit other immunocytes are called regulatory T cells (T_{reg}'s).

- Regulatory T cells play a key immunoregulatory role by eliminating or suppressing autoreactive T cells. Despite their indispensable role as negative regulators of excessive or autoreactive immune responses, T_{reg}'s can be co-opted by tumors to diminish or block anti-tumor immune responses.
- In addition to many receptor–ligand interactions that induce or intensify immune responses, there are immune checkpoints that negatively regulate immune responses, dampening their intensity and ensuring that they are self-limiting. Two receptors, CTLA-4 and PD-1, are key receptors for the mediation of checkpoint inhibition. Though essential agents of normal immunophysiology, they can also reduce anti-tumor responses to the point that they become ineffective.
- The CTLA-4 and PD-1 mediated checkpoints exert their effects in different anatomical locations. In lymph nodes, the stimulatory effect of engagement of CD28 on T cells with the co-stimulatory ligands, CD80/86, is counterbalanced by engagement of CD80/86 with the inhibitory receptor CTLA-4, preventing excessive T-cell activation. In peripheral tissues, the intensity and duration of the T-cell response is dampened by engagement of the inhibitory receptor PD-1, borne by responding T cells with its PD-L1/2 ligand displayed by other cells within various tissues.
- Natural killer (NK) cells are cytotoxic cells that kill cells that lack proper levels of cell surface MHC class I molecules. Given the strong selective pressure imposed by CTLs, some cancer cells contrive to shut down their display of MHC-I and escape cytotoxic T-cell attack. NK cells provide a bulwark against this strategy. In addition, NK cells are endowed with receptors that can detect the display of certain stress-induced ligands on the surface of cells and kill them.
- NK cells have receptors for the Fc regions of certain antibody classes, allowing them to bind via their FcRs to antibody-coated cells and kill them via the process of antibody-dependent cellular cytotoxicity (ADCC).

- Macrophages represent a versatile category of phagocytic cells that display a spectrum of phenotypes ranging from the anti-tumor highly phagocytic M1 state to the protumor M2 state that supports vascularization and tissue repair and secretes the immunosuppressive cytokines IL-10 and TGF-β. Macrophages possess Fc receptors and can be induced to kill antibody-targeted cells by antibody-dependent cellular phagocytosis (ADCP) or ADCC.

Thought questions

1. What clinical data and experiments using animal models do you believe provide the most compelling evidence that the immune system plays a significant role in suppressing the appearance of solid tumors?
2. Most of the antigenic differences between normal cells and tumor cells are not displayed on the cell membrane but reside in the cell's interior. Nevertheless, the presence of these antigens, most of which are proteins, are often detected by the immune system and responses are mounted against them. How and on what platforms are specific portions of these interior antigens displayed on the cell surface?
3. Some individuals have congenital defects in antibody production that render them unable to make antibody responses. Despite this deficiency, would you expect many of these individuals to retain the ability to mount many of the most consequential immune responses to cancer? Explain why you answered as you did.
4. The CD4 category of T cells encompasses multiple subtypes of cells. Do any of these make important contributions to the immune response against cancer, and which, if any, would you expect to be a powerful inhibitor of anti-tumor responses? Provide justifications for your responses.
5. Even after tumors come under immune attack, all too often they manage to escape elimination. How would you account for the failures of the immune system to eradicate many of the tumors it recognizes and mounts an initially effective attack against?
6. Adaptive and innate immunity are distinct, but often collaborative, arms of the immune system. Can you describe specific examples that illustrate the harnessing of innate/adaptive collaborative interactions to mount attacks on cancer?
7. Consider the following immune responses: (1) the activation of anti-tumor CD8+ T cells; (2) the activation of anti-tumor CD4 T cells. What effect, if any, would you expect blockade of CTLA-4 by anti-CTLA-4 antibodies to have on either or both of these processes? Justify your response.
8. Tumors often provoke immune responses that result in attacks upon them. However, in many instances these immune attacks fail to

eliminate the tumor and become increasingly ineffective at limiting tumor growth. How would you explain the ability of cancers to evade control or elimination by the immune system?

Supplementary Sidebars

Supplementary Sidebar 15.1 Antibody and T-cell receptor diversity are generated by somatic rearrangement of germ-line genes

The immunoglobulin (Ig, antibody) genes and the T-cell receptor genes (TCR) generate diverse antigen-combining regions through similar mechanisms involving the rearrangement of preexisting germ-line DNA segments. As shown in Figure 15.6A and B, antibody molecules and B-cell receptors are tetramers of two heavy (H) and two light (L) chains. While only a single heavy-chain-encoding locus exists (**Figure S15.1A**), light chains can be encoded by either of two alternative light-chain genes, termed κ and λ. In humans, each of the light-chain loci (*above*) encodes a series of V segments, ~30 in the case of the V_{λ} locus and ~35 in the case of the V_{κ} locus. A small cohort of J_{λ} and J_{κ} (joining) segments and C (constant) region segments encode the remaining portions of the light chains. The single heavy-chain locus (*below*) is more complex, carrying ~40 V_H, ~25 D_H, and 6 J_H segments and a C_{μ} segment lying to the right. In addition, there are a number of other constant region segments to the right/downstream of C_{μ} (*not shown*). The VJ and VDJ segments in the light and heavy gene loci are responsible for the diverse antigen-combining abilities of immunoglobulins. The L segments (*open rectangles , white*) encode short N-terminal "leader/signal" segments that enable co-translational insertion of nascent polypeptide chains into the endoplasmic reticulum. During the rearrangements that generate functional antibody genes (Figure S15.1B), V, J, and C segments of the light chains (*left*), and V, D, J, and C segments of the heavy chains (*right*), are fused to assemble the coding sequences of these subunits of the mature, functional antibody molecule. Each V, J, and C segment is chosen randomly from the corresponding germ-line repertoire of the V, the J, and the C segments, respectively, resulting in a fused reading frame, such as $V_{\kappa 31}$ $J_{\kappa 2}$ in the case of a kappa light chain, or V_{H17} D_{H11} J_{H3} in the case of a heavy chain. (Not included here are the various L-chain leader oligopeptide segments, which are usually cleaved off during the maturation of antibody proteins. In addition, in the case of the heavy chain locus, are fusions to a number of alternative C_H segments (*right, not shown*), which can result in joining a number of alternative constant regions to a rearranged VDJ variable region; these fusions, the products of C region "switching," create alternative "classes" of antibody molecules, all of which may share the same antigen-binding domain.)

Figure S15.1 The stochastic rearrangements of V region DNA segments creates a broad diversity of antigen-binding receptors and antibodies (A) The antigen-combining domains of the heavy (H) and light (L) antibody chains and B-cell receptors are generated by rearrangements and fusions of variable (V, *red*) and joining (J, *yellow*) DNA segments (in the case of the two light chain loci) and, in the case of the heavy chain locus, of V, diversity (D, *green*) and J segments. Following formation of the DNA segments encoding these antigen-binding domains, the resulting fusion segments are then fused with constant (denoted by C) region-encoding segments (*blue*). The entire repertoires of the C region segments are not illustrated here. (C) A diverse repertoire of T-cell receptors is generated by a similar process (*not shown*) that involves the rearrangement and joining of DNA segments encoding each of the distinct immunoglobulin chains of the T-cell receptor. (Some of the content of this sidebar is based on or modified from K. Murphy, C. Weaver and L. Berg (eds.) *Janeway's Immunobiology, 10th ed*. New York: W. W. Norton, 2022.)

In addition to the rearrangement of germ-line-encoded gene segments described above, additional antibody diversity is provided subsequently by the enzyme-mediated mutation of the DNA segments encoding variable regions of rearranged heavy and light chains. Following antigen stimulation and signals from the follicular subset of CD4 helper T cells (T_{FH}), some B cells undergo the antibody class switching mentioned above and experience a 100,000-fold increase in the mutation rate of their rearranged antibody genes. These mutations are caused by the induction of activation-induced deaminase (AID), a cytidine deaminase of the APOBEC family. Because the mutations occur in somatic cells rather than germ cells and the mutation rates induced within these short regions of genomic DNA are very high, the process is often called somatic hypermutation. Most of the mutations occur within or close to the variable regions of rearranged antibody genes. Some of these mutations lie within the portions of V region genes destined to encode the antigen-combining sites of antibody genes. Some of the AID-induced mutations affect and thereby diversify the binding affinities of the encoded V regions with antigens. Those that increase affinity have significant consequences. Higher-affinity antibodies bind their cognate antigens more tightly, more rapidly, and at lower concentrations of antigen and antibody. Although these attributes, induced by the action of AID, are generally desirable, some of the mutations caused by AID take place inadvertently in other unrelated genes throughout the genome and have the potential to generate mutant proteins that are oncogenic.

A similar scheme of gene rearrangements that operate to generate the αβ chains of the T-cell receptor is illustrated in Figure S15.1C. These two chains are encoded by unlinked genetic loci but are organized on the same principle as the immunoglobulins and participating genetic segments are rearranged by the same molecular machinery. However, T cells do not express AID and therefore, unlike antibody genes, T-cell receptor genes do not undergo somatic hypermutation. (Modified from K. Murphy, C. Weaver and L. Berg (eds.), Janeway's Immunobiology, 10th ed. New York: W.W. Norton, 2022.)

OceanofPDF.com

Glossary

activation-induced deaminase
: A cytidine deaminase that introduces point mutations in already-rearranged immunoglobulin genes, preferentially in their V regions, thereby diversifying antigen-binding specificities of the encoded immunoglobulins.

somatic hypermutation
: Enzyme-mediated process, notably that effected by activation-induced deaminase, that creates point mutations in the already-rearranged immunoglobulin genes, largely focused on their V region-encoding segments and generating greatly increased antigen-binding diversity. *See also* **activation-induced deaminase**.

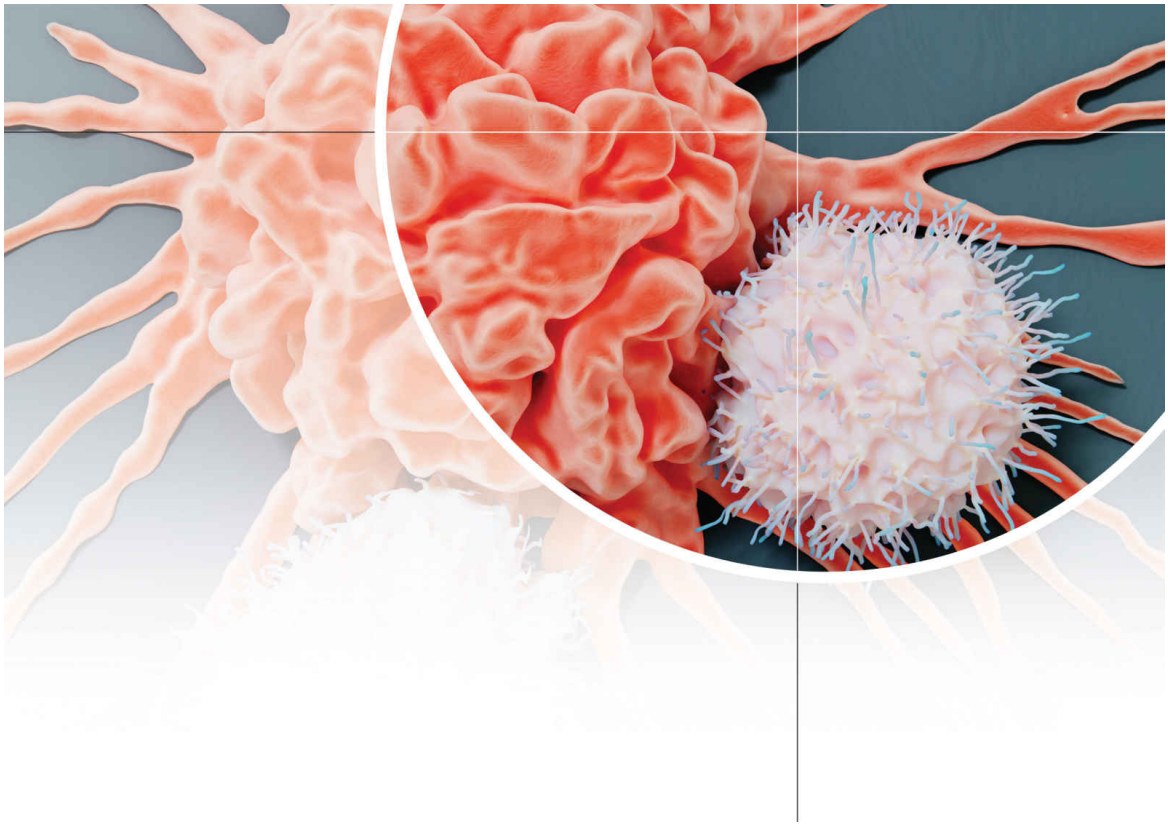
Chapter 16
Cancer Immunotherapy



A scanning electron microscope image of a large cell with two smaller cells next to it. The larger cell has an undulating surface and long projections extending outward. The two smaller cells look like cotton balls with short wavy extensions covering their surface.

[I]n animals, ... inheritable genetic changes must be common in somatic cells and a proportion of these changes will represent a step toward malignancy. It is an evolutionary necessity that there should be some mechanism for eliminating or inactivating such potentially dangerous mutant cells and it is postulated that this mechanism is of immunological character.

Macfarlane Burnet, immunologist,1964

As described in the last chapter, research conducted over the past several decades has left us with a rich, detailed accounting of the workings of the immune system. Although much remains to be learned, the existing body of information on immunological functions has provided us with a broad and deep foundation for translation into clinical care, that is, the development of immunotherapies focused on harnessing the powers of the immune system to eliminate clinically diagnosed tumors. At present, the field of cancer immunotherapy is exploding, with hundreds of different immunotherapies being considered or developed, all of which draw directly from the lessons we learned in Chapter 15.

Much of the current enthusiasm for cancer immunotherapies comes from the perception that most of the low-molecular–weight pharmacological treatments of cancer have seemingly reached the limits of what they are capable of providing, and that truly curative therapies will need to be sought from an entirely different therapeutic approach, specifically immunotherapy. This explains the depth and breadth with which cancer immunotherapies are laid out in this chapter.

Drawn in broad strokes, these immunotherapies can be placed into three categories. The most straightforward are those that provoke the immune system to develop reactivity with tumor cells and neutralization of the infectious agents that cause their formation; these protocols proceed via clinical strategies that resemble traditional vaccination by providing antigens that either prevent tumor formation or provoke the development of immunity against already established tumors. A second major strategy can be depicted as passive immunization, in which patients under treatment are supplied with antibodies or cells of various sorts that, for one or another reason, the patients' own immune systems have been incapable of developing on their own.

And finally, the third thrust of modern immunotherapy derives from treatments that reveal otherwise-inapparent immunities that patients' own immune systems have successfully developed but that, for various reasons, have been blocked by various immunosuppressive mechanisms. As we shall see, tumor immunology, including immunotherapy, represents a rapidly advancing field; indeed, it is the most dynamic and innovative area of contemporary cancer research. At present, we have only begun to understand its potential for developing truly effective treatments of neoplastic diseases, many of which have proven resistant to existing therapies.

OceanofPDF.com

Glossary

passive immunization
: Procedure in which the immune responses of an organism are supplemented or strengthened through the introduction of immunological agents, usually antibodies or immunocytes, of foreign origin.

16.1 Vaccination can prevent cancer caused by infectious agents

We begin our exploration of immunotherapies with vaccination, immunology's oldest, safest, most widely used, and to date most successful technology. These immunotherapies derive directly from more than two centuries of experience in generating protection against infectious agents via vaccination. Decades of epidemiological, clinical, and laboratory studies have shown that infectious agents are responsible for about 20% of cancers. As shown in **Table 16.1** at least seven viruses, one bacterium, and three parasites have been implicated as etiological agents in cancer pathogenesis. Some of these are directly involved and others play important but indirect roles in oncogenesis. Given the demonstrated power of immunization to neutralize infectious agents, these agents represent attractive targets for immunization undertaken to *prevent* the appearance of the cancers that they cause.

Table 16.1 Infectious agents implicated in human cancer causation

Classification	Infectious agent	Mode of carcinogenesis (mediator)	Human malignancy	Transmission
herpesvirus	EBV	direct (oncogene)	lymphoma; some nasopharyngeal carcinomas	saliva, transfusion, and sexual contact
delta retrovirus	HTLV-1	direct (oncogene)	adult T cell lymphoma	sexual contact, needle sharing and transfusion

Classification	Infectious agent	Mode of carcinogenesis (mediator)	Human malignancy	Transmission
papilloma virus	HPV	direct (oncogene)	cervical cancer, some oropharyngeal, genital and anal cancers	sexual contact
herpesvirus	KSHV (also called HHV8)	direct (oncogene)	Kaposi sarcoma and others	salivary spread in endemic area; sexual spread in nonendemic areas
polyoma virus	MCPyV	direct (oncogene)	skin cancer	skin to skin contact and contact with virus-contaminated surfaces
hepatitis virus	HBV	indirect (chronic inflammation)	liver cancer	transfusion, needle sharing, and sexual contact
hepatitis virus	HCV	indirect (chronic inflammation)	liver cancer	transfusion, needle sharing, and sexual contact

Classification	Infectious agent	Mode of carcinogenesis (mediator)	Human malignancy	Transmission
lentivirus	HIV	(immunosuppression)	increased risk of many cancers, including Kaposi sarcoma, lymphoma, and others	sexual contact and transfusion
bacterium	*H. pylori*	(inflammation)	some stomach cancers and gastric tissue associated lymphomas	perhaps by consuming contaminated water and foods
helminth	*Opisthorchis viverrini*	(generation of oxidizing agents?)	cholangiocarcinoma	consumption of raw or undercooked fish from fresh waters of Southeast Asia
helminth	*Shistosoma hematobium*	(generation of oxidizing agents?)	bladder cancer	Contact with fresh water snails infected with S. hematobium
helminth	*Clonorchis sinensis*	(generation of oxidizing agents?)	cholangiocarcinoma	consumption of raw or undercooked fish from

Classification	Infectious agent	Mode of carcinogenesis (mediator)	Human malignancy	Transmission
				fresh waters of many regions of Asia

EBV, Epstein–Barr virus; HTLV-1, human T cell leukemia virus-1; HPV, human papilloma virus; KSHV, Kaposi sarcoma herpes virus, also known as human herpesvirus 8 (HHV8); MCPyV, Merkel cell polyoma virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus.

In fact, all of the infectious agents that are directly involved in driving oncogenesis are viruses. The five known, widely acting oncogenic viruses—HPV, HTLV-1, EBV, MCPyV, and KSHV—all express viral oncoproteins. As argued in Section 8.5, these viruses deploy virus-encoded oncoproteins in order to convert the intracellular environments of infected cells into ones that support efficient viral replication. Accordingly, the evolution of these viruses has been dictated by their need to optimize their mechanisms of proliferation rather than optimizing cell transformation and the formation of tumors. Each of these viruses is considered *directly oncogenic* because one or more of its virus-encoded gene products operates to perturb the intracellular signal transduction machinery, as described previously in Chapters 8 and 9. Central to our thinking here is the notion that the ability of these viruses to transform cells in a fashion that leads to tumorigenesis requires the continued presence of the viral genomes in the descendants of initially infected cells —a mechanism first described in Section 3.3 in the context of Rous sarcoma virus transformation. In the absence of continued expression of virus-encoded oncoproteins, during the earlier stages of tumorigenesis, some virus-transformed cells are likely to revert to a non-neoplastic state.

The other six agents, including two viruses (HBV and HCV), one bacterium (*Helicobacter pylori*), and three flatworm parasites (*Schistosoma haematobium*, *Opisthorchis viverrini*, and *Clonorchis sinensis*), are *indirectly oncogenic*, in that infection by these agents induces localized, persistent inflammation within a tissue, which in turn favors the outgrowth of tumors. The inflammation induced by these agents reflects normal responses by the immune system that are designed to rapidly and effectively eliminate infectious agents; however, because these infections are not successfully cured, chronic localized inflammation ensues, which in turn creates

a hospitable tissue microenvironment for the outgrowth of pre-neoplastic and neoplastic growths, as described in Section 11.13.

These persistent inflammatory states usually feature the continuing release of a variety of tumor-promoting cytokines, chemokines, and prostaglandins as well as the generation of mutagenic reactive oxygen species (ROS; see Section 12.4). This explains why prevention of infections by these agents or their timely eradication from the body can avoid the cancers that they might otherwise cause. In principle, this might be accomplished in either of two ways: the use of antimicrobial drugs, such as antibiotics being employed to eliminate *H. pylori*, or vaccinations, such as those used to confer immunity to future infections by neutralizing various cancer-inducing agents. Importantly, in the case of the class of tumors induced by indirectly oncogenic infectious agents, the clearing of these agents from the body's tissues will not necessarily affect the continued growth and viability of already-established tumors simply because, once formed, these tumors no longer depend on the inflammatory signals that fostered their development in the first place.

Prophylactic vaccines, which are designed to prevent infections by cancer-inducing agents, represent by far the largest group of vaccines currently used in the clinic. If successful, they prevent the formation of the tumors that are caused by these agents. Therapeutic vaccines, in contrast, are used to treat already-established disease; there are very few examples of this type of vaccine employed clinically, in part for reasons described above. When considering and comparing these two alternative approaches, we must keep in mind that, in terms of reducing morbidity and mortality from neoplastic disease, prevention is always vastly more effective than attempts to treat existing disease, sometimes by orders of magnitude.

Two prophylactic vaccines have proven to be highly effective in lowering the incidence of cancers caused by two infectious agents. One of these prevents infection by hepatitis B virus (HBV), the agent responsible for most hepatocellular carcinomas (**Sidebar 16.1**). The other vaccine prevents infection by oncogenic human papillomaviruses (HPVs), the cause of most (~99%) cases of cervical cancer and cancers at other sites as well. Both of these vaccines have had significant impact in reducing the incidence of the cancers caused by the infectious agents they protect against.

Sidebar 16.1 Hepatitis B virus infections led to hepatomas in Taiwanese government workers

Epidemiological studies usually yield outcomes that make it difficult to discern a strong correlation between occasional exposure to certain environmental factors and

a subsequent moderately increased risk of cancer. The incidence of liver cancer, however, varies dramatically throughout the world, making it possible to strongly associate this disease with specific causative factors. In certain parts of the world, including much of Asia—especially China and sub-Saharan Africa—hepatocellular carcinomas (HCCs, also known as hepatomas) are one of the leading causes of death due to cancer. In stark contrast, liver cancer ranks 25th as a cause of cancer-related deaths in the United States.

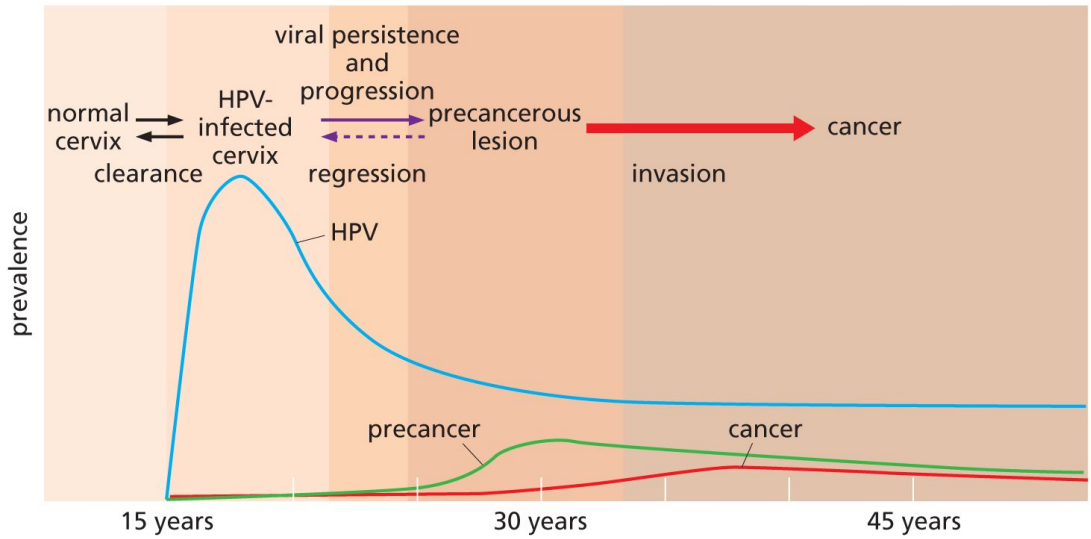
A stunning correlation can be made between hepatitis B virus (HBV) infections and susceptibility to liver cancer. At the beginning of an epidemiologic study undertaken in 1975, the HBV status of 22,707 men in government service in Taiwan was determined by measuring, among other parameters, the presence of viral antigens in their blood. The causes of deaths in this cohort were then chronicled over the next decade. By 1986, death from hepatocellular carcinoma had claimed 152 of the 3454 men who were initially positive for HBV viral antigen, but only 9 of the 19,253 men who were negative for this antigen in their blood. The relative increased risk of dying from his disease if one carried viral antigen in the circulation (which is indicative of an active HBV infection in the liver) was calculated to be 98.4. This means that an individual afflicted with chronic, active HBV infection experienced an almost 100-fold increased risk of contracting and dying from this cancer compared with someone who lacked viral antigen in his liver and was apparently uninfected. These numbers contrast strongly with most epidemiologic correlations made between specific exposures of patients to suspected carcinogens and disease incidence, where relative risk of disease is often only two to threefold, often hovering on the borderline of statistical significance.

OceanofPDF.com

16.2 Vaccination against human papillomaviruses prevents cervical cancer

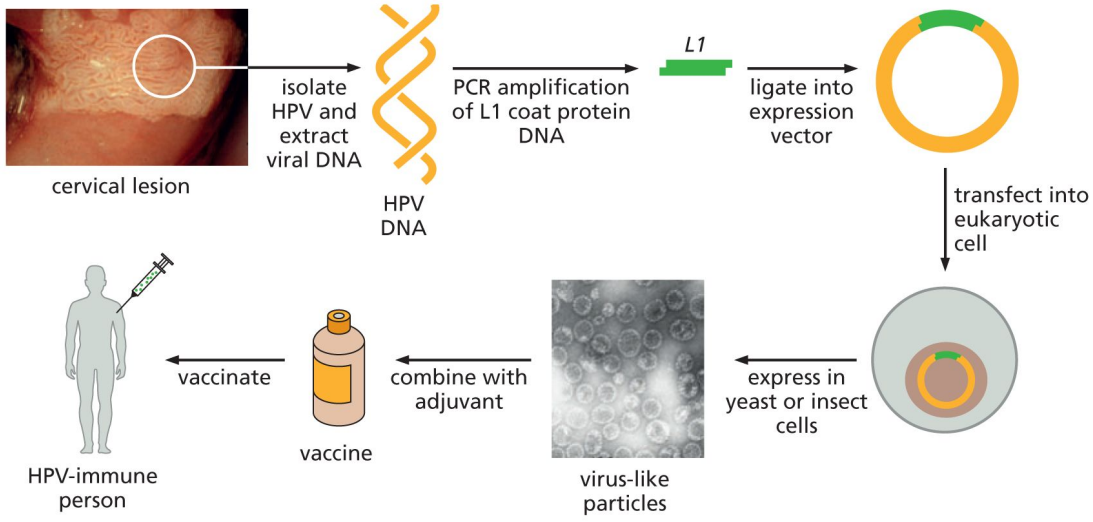
Because the oncogenic effects of HPVs are direct rather than indirect, we will examine vaccination strategies to prevent HPV infection in some detail. HPVs represent a major human carcinogen, being sexually transmitted and responsible for at least 99% of all cervical cancers and about 4.5% of total cancer incidence worldwide. In addition to cervical carcinoma, other anogenital cancers (88% of carcinomas of the anus, 25% of the vulva, 78% of the vagina, and 50% of the penis) and a significant fraction of head-and-neck squamous cell carcinomas (HNSCC) can be traced back to HPV infections. In the United States, the numbers of HPV-linked oropharyngeal carcinomas (OPCs), a subset of HNSCCs, now exceed the numbers of cervical cancers diagnosed annually. Although more than 150 distinct HPV types have been identified, only 12 of these have been associated with cervical cancer and other HPV-induced cancers, with just two HPV types—HPV16 and HPV18—being responsible for 75% of HPV-induced cancer.

Epidemiological studies demonstrate that in the United States, the prevalence of HPV infection in females increases rapidly in the mid-teens, a consequence of the onset of sexual activity (**Figure 16.1A**). Many years elapse between the times of infection and the progression to cancer by the small proportion of HPV-infected people who actually develop clinically detectable cancers. By now it has become clear that vaccination to prevent infection should occur in boys and girls during childhood or early adolescence, at a time before men (the vectors of the disease) and women become sexually active.



A graph displays the prevalence of and progression of H P V infections over time. There are five phases. A normal cervix can be infected with H P V. If clearance occurs, it returns to a normal cervix. If viral persistence and progression occurs, a precancerous lesion forms. If regression occurs, the cervix will return to normal. If invasion occurs, it becomes cancer. On the x axis is age from 10 to 50 years. From 10 to 15 years there is no H P V. From 15 to 22 years, prevalence of H P V increases rapidly to a peak at 18 years and then starts to decline. Prevalence of precancer and cancer is low. Prevalence of H P V continues to decline and plateaus at a moderate level around age 30. This is also when the prevalence of precancer peaks. The prevalence of cancer peaks around age 37 but is still lower than the prevalence of H P V and precancer.

(A)



A diagram shows the production and implementation of anti-H P V vaccines. H P V is isolated from a cervical lesion and the viral D N A is extracted. From the H P V D N A, P C R amplification of the L 1 coat protein is performed. This is ligated into an expression vector that is transfected into a eukaryotic cell. The vector is expressed in yeast of insect cells that produce virus like particles. These particles are combined with an adjuvant to make a vaccine. The vaccine is used to vaccinate a person, rendering them immune to H P V.

(B)

Figure 16.1 Prevention of HPV infections More than 99% of human cervical carcinomas are caused by human papillomavirus (HPV) infections, which has led to the development of multiple anti-HPV vaccines that block viral infections and thereby prevent this cancer. (A) The natural history of HPV and cervical cancer. In women, the prevalence of transient HPV infection (*blue curve*) begins in the early teens and peaks during the 20s, paralleling the initiation of sexual activity. Cervical precancerous conditions (*green curve*) begin to appear approximately 10 years later. The peak prevalence of invasive cancers (*red curve*) is seen between ages 40 and 50. The development of precancerous lesions depends on the persistence of viral infection, because viral oncogenes and encoded oncoproteins are essential for the progression of the precancerous lesions to cancer and in many cases remain important for the growth and maintenance of the resulting cancers. (B) Anti-HPV vaccines were produced by extracting DNA from the virions of various HPV strains, and in each case the segment encoding L1, the major capsid protein, was amplified by PCR using specific primers; the amplified DNA was ligated into an expression vector and introduced into yeast cells for protein production. The resulting L1 protein assembles spontaneously into virus-like particles (VLPs), which are then introduced together with a suitable adjuvant (a substance that enhances the immune response) to formulate a vaccine that is subsequently injected into humans. (A, adapted from M. Schiffman & P.E. Castle, *N. Engl. J. Med.* 353:2101–2104, 2005. With permision from Massachusetts Medical Society. B, adapted from I.H. Frazer, G.R. Leggatt & S.R. Mattarollo, *Annu. Rev. Immunol.* 29:111–138, 2011. With permission from Annual Reviews.)

The small genome of HPV (see Section 3.4) limits the number of proteins encoded by HPV to the capsid proteins and several other proteins that foster the replication of its DNA genome. L1, the more abundant of HPV's capsid proteins, can be induced to assemble into virus-like particles (VLPs) *in vitro* in the absence of viral DNA and other capsid proteins. These particles are immunogenic and, upon injection, induce neutralizing antibodies, which has been exploited for the development of a variety of vaccines against HPV (Figure 16.1B). The VLP-based vaccines are safe because the injected vaccine virions lack the viral DNA needed for viral replication; at the same

time, they are capable of inducing a strong protective immune response because the VLPs display the L1 target antigen in a stereochemical configuration that is virtually identical to the way it is displayed by intact virus particles.

The effectiveness of the VLP-based vaccine strategy has been repeatedly demonstrated in large clinical trials, including tests of versions of the vaccine that involve L1 capsid proteins (and resulting VLPs) from an increasing number of HPV types. Although 70% of cervical cancer is caused by just two types, HPV 16 and HPV 18, immunizations against additional virus types have been added with each successive iteration of the vaccine, eventually including VLPs produced by HPV types 31, 33, 45, 52, and 58; these additional HPV types are known to make modest but real contributions to the causation of cervical cancer. In addition, VLPs from HPV types 6 and 11 antigens have been included in these polyvalent vaccines because these types cause anal and genital warts. In 2014, the FDA approved Gardisil9^{TM}, a nonavalent vaccine containing VLPs made by all nine of these HPV types. This vaccine is 96.8% effective in preventing cervical cancer.

16.3 Therapeutic vaccination is a potential treatment for cancer

An alternative strategy for developing anti-cancer vaccines holds the promise of treating established tumors by developing immune recognition of cancer cells rather than the agents that previously caused them. As we read in Section 15.7, the observation that CD8+ cytotoxic T cells can develop the ability to recognize and lyse cancer cells displaying certain antigens has encouraged attempts to use therapeutic vaccination to induce potent anti-tumor responses. In these cases, vaccination is accomplished by administration of specific tumor antigens under conditions that provoke adaptive immune responses.

In principle, the more general strategy of targeting already-formed cancer cells of both viral and nonviral origin offers the advantage that it enables attacks on both primary tumors and metastatic colonies disseminated throughout the body of a cancer patient. Furthermore, should cancers return after being successfully controlled and caused to regress, memory anti-tumor immune responses offer the potential to recognize and thwart such clinical relapses. Despite the appeal of immunization to treat existing cancers, significant obstacles have blocked the path to its widespread use in clinical practice. The most important of these involve the mechanisms of immune escape and evasion discussed in Section 15.13, some of which derive from the ability of tumors to hide within immunosuppressive microenvironments that they assemble around themselves.

Nonetheless, despite clear and formidable challenges, a number of efforts have been launched to develop effective therapeutic cancer vaccines against established tumors. These fall into one of two major strategies: direct delivery of antigen and delivery of antigen loaded on dendritic cells. Direct delivery can provide a wide variety of putative tumor antigens and has the appeal of simplicity. However, it is totally dependent on *in vivo* host processes to perform the key steps of antigen uptake and presentation by professional antigen-presenting cells (APCs). The alternative involves the loading of dendritic cells or dendritic-like cells *ex vivo* and their subsequent delivery to the patient in order to ensure the *in vivo* presentation of antigens by cells capable of activating T-cell-mediated anti-tumor immune responses.

Direct delivery uses a variety of vaccination strategies to provoke tumor antigen responses. These include injection of (1) the antigenic protein or peptide directly into the tumor or the systemic circulation, (2) the RNA encoding this antigen, or (3) the DNA encoding this RNA. While direct injection of the protein antigen represents the

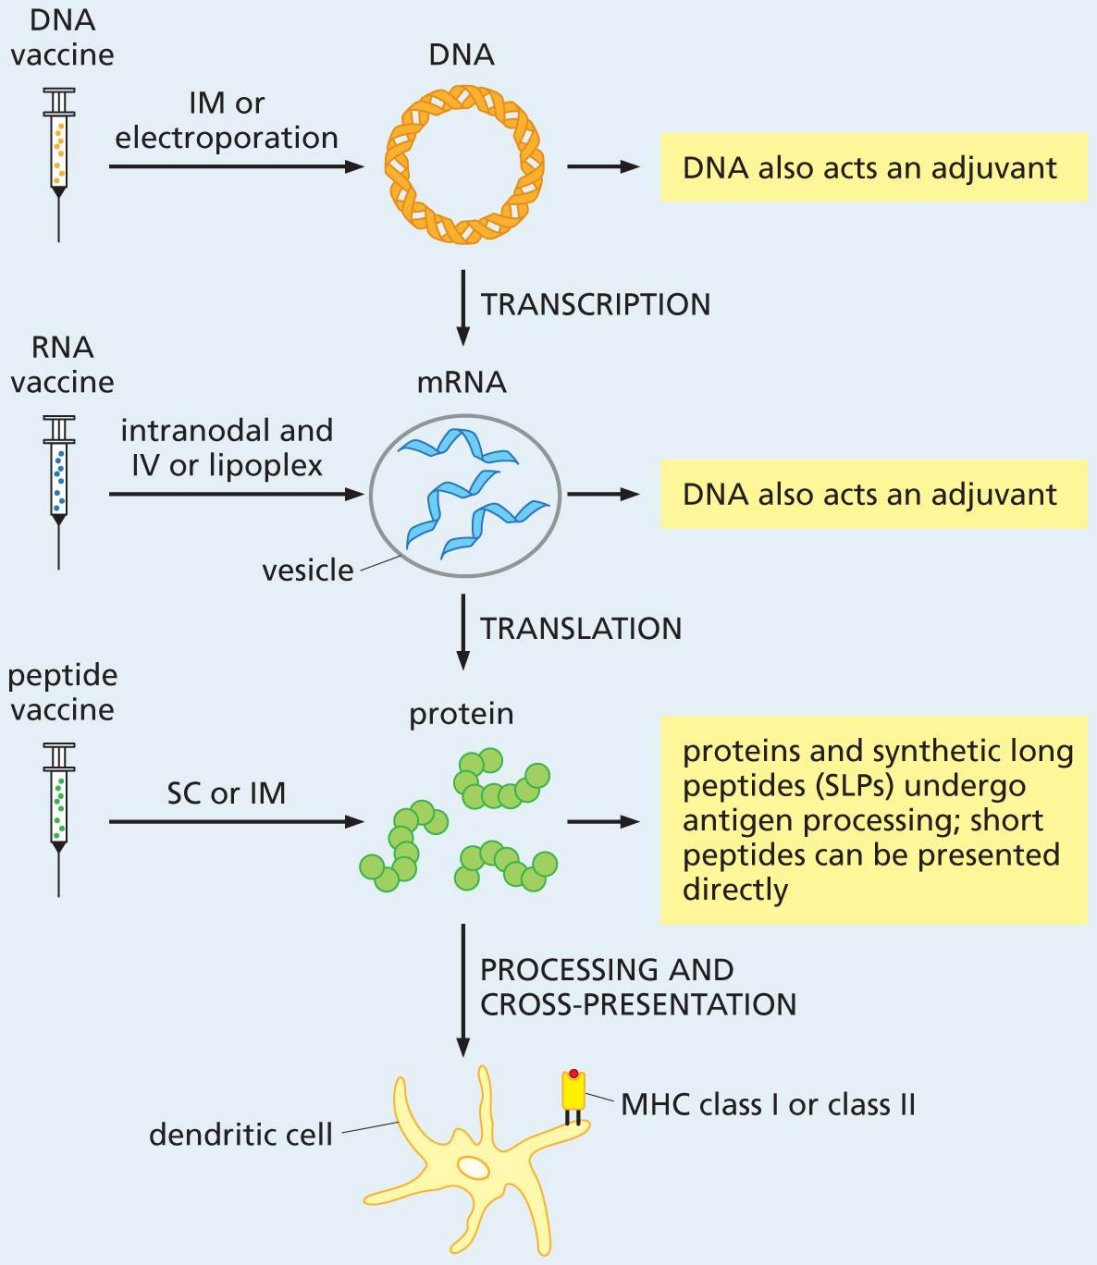
most straightforward approach, the use of RNA or DNA has certain advantages. Transfection with either RNA or DNA makes it possible to include in the vaccine inoculum other molecular templates that encode an adjuvant protein, such as a cytokine, in addition to the target antigen. Although promising RNA-based cancer vaccines have begun to appear (**Sidebar 16.2**), there may also be clinical situations in which more stable DNA vaccines have advantages over the more labile RNA vaccines.

Sidebar 16.2 RNA vaccination shows promise for the treatment of melanoma

A variation on the RNA vaccine technology that has been deployed so effectively to generate highly efficacious coronavirus vaccines shows promise for therapeutic cancer vaccination. Melanoma patients, whose tumors had progressed despite previous treatment and expressed at least one of a set of melanoma antigens, specifically NY-ESO-1, MAGE-A3, TPTE, or tyrosinase, were given a vaccine composed of mRNAs that encoded all four antigens. In an early-stage clinical trial, partial responses (shrinkage of a tumor) were seen in 26% of a cohort of 38 trial enrollees, all of whom were afflicted with unresectable stage III or IV melanomas. Moreover, the vaccine stimulated antigen-specific responses in both CD4+ and CD8+ T-cell populations.

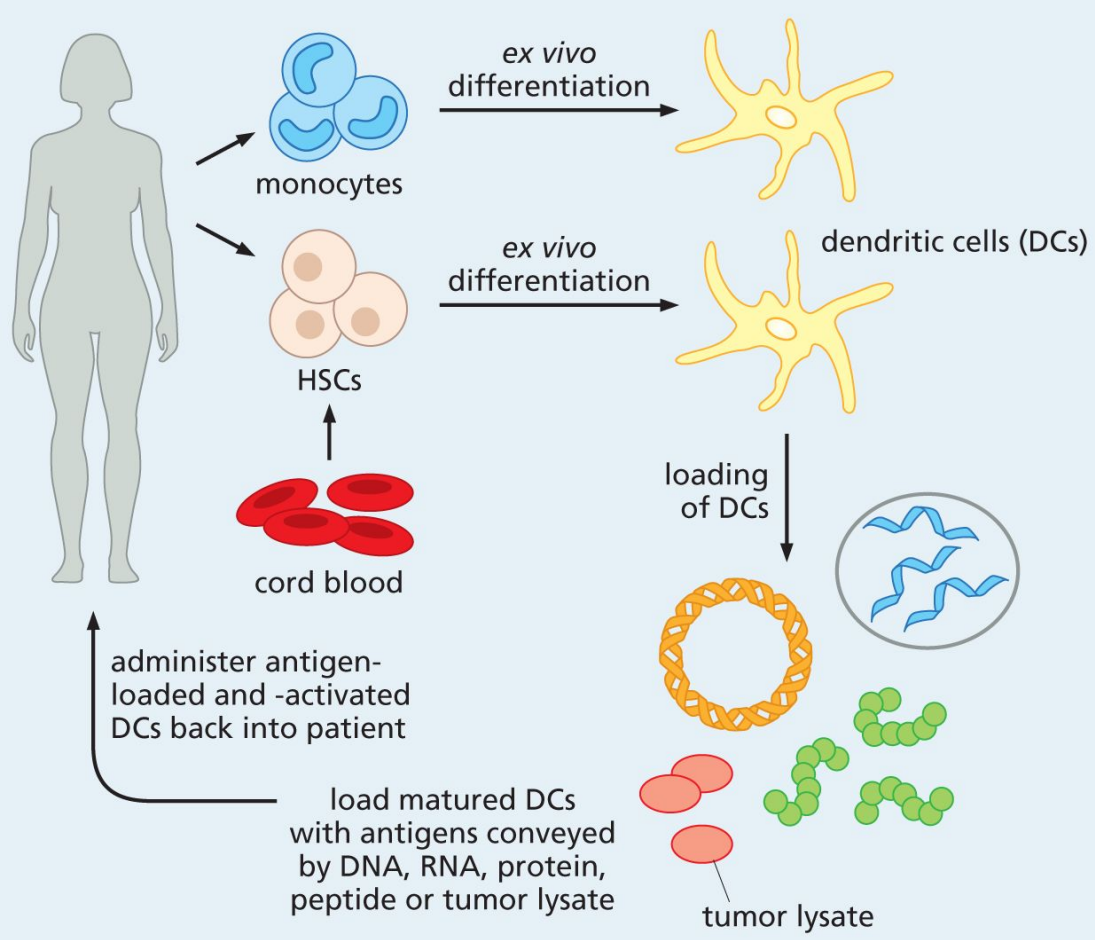
Strikingly, in some enrollees, the levels of antigen-specific CD8+ T-cell clones reactive with one of the vaccine-encoded antigens rose over the course of 8 weeks from undetectable levels prior to immunization to levels approaching 10% of circulating CD8+ T cells. Observations like these have encouraged investigation of the possibility that the addition of an appropriate immune checkpoint inhibitor (described in Section 16.9) may further increase the clinical efficacy of certain mRNA-based therapeutic cancer vaccines.

At this point the development of RNA-based therapeutic cancer vaccines is still in its early stages, and future work will surely extend exploration of this approach to cancer-specific tumor antigens. Efforts will be made to target established tumor antigens, such as the E6 and E7 oncoprotein drivers present in cancers of HPV etiology, notably cervical cancer and some head-and-neck squamous carcinomas (see Section 16.2). In addition, mutations present in tumor cell genomes, such as the point mutations that create Ras oncoproteins and thus potential neoantigens, come to mind as attractive targets of future vaccine development. Finally, the mRNA vaccine technologies developed in the context of anti-COVID vaccine manufacture make them well suited to the fabrication of personalized cancer vaccines targeting the neoantigen repertoires of individual patients. Indeed, a variety of strategies for vaccination against tumor antigens, including neoantigens, are under exploration (**Figure 16.3**).



A depiction of three different delivery routes for Direct presentation of a peptide antigen. The first involves subcutaneous or intramuscular injection of a peptide vaccine. Once delivered, proteins and synthetic long peptides undergo antigen processing; short peptides can be presented directly. PROCESSING AND CROSS-PRESENTATION by dendritic cells then follows, where the presentation uses M H C class 1 or 2. The second delivery route involves intranodal and I V or lipoplex administration of an R N A vaccine. Once arrived in a vesicle, the m R N A can undergo translation to a protein, and the rest proceeds as in route 1. D N A can also act as an adjuvant. The third delivery route involves intramuscular injection or electroporation.

The D N A undergoes translation to m R N A, and the rest proceeds as in route 2. D N A can also act as an adjuvant.
(A)



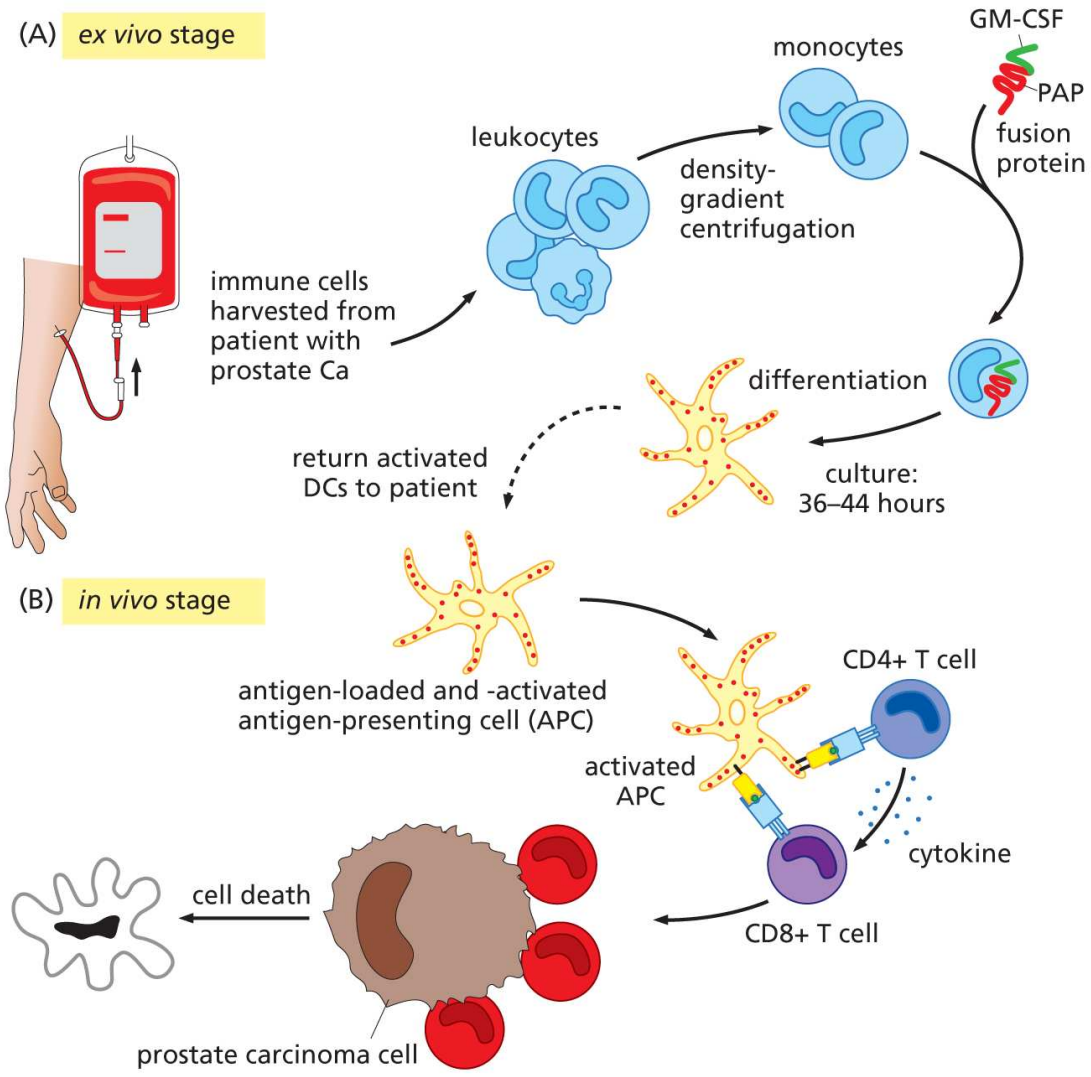
A cycle that begins with monocytes being extractes from a human patient, or with hematopeoietic stem cells being extracted from a human patient or from cord blood. The chosen cells undergo ex vivo differentiation. After the resulting dendritic cells mature, they are loaded with D N A, R N A, protein, peptide or tumor lysate. Once activated, the cells are administered back into the patient, completing the cycle.

(B)

Figure 16.3 Delivery platforms for cancer vaccines Antigen delivery strategies for cancer vaccines fall into two broad categories—direct delivery of antigen or agents encoding it to the patient's tissues and delivery by antigen-loaded dendritic cells. (A) Direct presentation of peptide antigen can be accomplished through three alternative routes. Direct delivery can be accomplished by injection of

antigen-encoding DNA or RNA, or by injection of protein itself or a synthetic long peptide (SLP) derived from it. With any of these three alternative delivery routes, the antigen can be processed to peptides in antigen-presenting dendritic cells (DCs). The machinery of cross-presentation by the DCs, which function as APCs, allows presentation of some peptides on MHC-I to CD8 T cells and presentation of some others on MHC-II to CD4 T cells. (B) Antigen-loaded dendritic cells can also be used in lymphoid tissues to deliver peptide antigen fragments in a three-step process. The first step involves induced differentiation *ex vivo* of host monocytes or hematopoietic stem cells (HSCs) into dendritic cells. Second, antigen-encoding construct is delivered to (loaded on) dendritic cells (*lower right*). Third, the resulting antigen-loaded DCs are infused back into the host. Abbreviations: IM = intramuscular, IV = intravenous injection, SC = subcutaneous injection, lipoplex = liposome-based and RNA delivery particles. (Adapted from M. Saxena, S.H. van der Burg, C.J.M. Melief et al., *Nature Rev. Cancer* 21:360–378, 2021. With permission from Nature.)

While lacking the simplicity of direct delivery, antigen-loaded antigen-presenting cells were used to develop the first therapeutic cancer vaccine to receive approval from the U.S. Food and Drug Administration (FDA). This vaccine, Sipuleucel-T, was developed for the treatment of prostate cancer. This particular vaccine strategy, schematized in **Figure 16.2**, while delivering only limited clinical benefit, has translated the concept of therapeutic vaccination into actual clinical practice.



A diagram shows the development of a therapeutic vaccination strategy for prostate cancer. Part A is of the ex vivo stage. Blood is drawn and immune cells are harvested from a patient with prostate cancer. These leukocytes are processed via density-gradient centrifugation to isolate monocytes. A fusion protein consisting of PAP and G M C S F is inserted into the monocyte. Differentiation occurs in a culture over 36 to 44 hours. The activated D Cees are returned to the patient. Part B is of the in vivo stage. The antigen loaded and activated antigen presenting cell, or A P C, binds to C D 4 plus T cells which release cytokines and transforms into a C D 8 plus T cell. These cells then bind to the prostate carcinoma cell and trigger cell death.

Figure 16.2 Development of therapeutic vaccination strategy for prostate cancer This therapeutic vaccination involves two stages, the first *ex vivo* and the second *in vivo*. (A) *Ex vivo* stage: An immunizing antigen is produced by fusing a cDNA encoding granulocyte–macrophage colony stimulating factor (GM-CSF)

and a second cDNA encoding prostatic acid phosphatase (PAP). The PAP (*red*)/GM-CSF (*green*) fusion protein generated is introduced into a cancer patient's monocytes. The GM-CSF portion of the fusion protein induces the differentiation of monocytes into antigen-presenting cells (APCs). The PAP portion corresponds to a prostate-specific antigen that is widely expressed in prostate carcinoma cells. PAP undergoes antigen processing in the monocyte-derived APCs, resulting in loading of PAP peptide fragments onto MHC proteins. This population of monocytes and induced APCs is infused into the cancer patient. (B) *In vivo* stage: Following their introduction into the patient, these antigen-loaded and -activated APCs present antigen to CD4 (*blue*) and CD8 (*purple*) T cells, leading in turn to the activation of PAP-specific CD4 and CD8 T cells. Cytotoxic CD8 (*red*) cells are shown engaging and killing a PAP-expressing prostate cancer cell (*brown*). (Adapted from J.A. Garcia, *Ther. Adv. Med. Oncol*. 3:101–108, 2011. With permission from SAGE.)

As much a process as a product, preparing the Sipuleucel-T vaccine involves the harvesting of peripheral blood mononuclear cells from a prostate cancer patient. These cells are then activated in culture by exposing them to recombinant human GM-CSF molecules that have been chemically linked to human prostatic acid phosphatase (PAP), an antigen that is expressed at elevated levels in advanced prostate carcinomas. The GM-CSF portion of the hybrid PAP-GM-CSF protein binds as a ligand to cognate GM-CSF receptors displayed by the patient's monocytes and induces their differentiation into antigen-presenting dendritic cells (DCs). At the same time, some of the receptor-bound hybrid protein–ligand molecules, like many receptor–ligand complexes, are internalized into these DCs, where they undergo proteolysis and processing for subsequent antigen presentation on MHC molecules.

Prostate cancer patients are infused with the resulting *ex vivo* differentiated, antigen-loaded DCs, which should then migrate to the recipient's lymphoid tissues. Once arrived in these tissues, these DCs, using their cross-presentation powers (see Section 15.7), should present resulting peptide antigens—notably those derived from cleavage of PAP—via their MHC class II molecules to CD4+ helper T cells and via their class I molecules to prime the naive CD8+ T cells. Among other consequences, this antigen presentation should result in the generation and proliferation of PAP-specific cytotoxic T lymphocytes (CTLs) in the patient's lymphoid tissues, which thereafter have the potential to attack prostate cancer cells displaying the PAP protein antigen. To be sure, normal prostate cells will be targeted as well, but other cell types will be spared from PAP antigen-specific attack.

Sipuleucel-T is described here largely because of the interesting logic that led to its development and introduction into the clinic. In reality, the clinical benefit that it offers has been modest, with increases in time to progression and overall survival of several

months. At present it is difficult to know whether similar strategies will prove useful in developing immunotherapies that yield truly striking responses in patients afflicted with a variety of other cancer types.

Several factors will be important in determining the degree to which these and similar vaccines are successful. These include the target antigen's degree of foreignness, the widespread expression of the target antigen within a tumor, and whether its proteolytic cleavage gives rise to peptides that can be effectively presented by the MHC molecules displayed on the surface of a patient's cells.

Also, in the case of tumor antigens that are formed as a consequence of somatic mutations, the identity of the affected gene—whether it is a driver or passenger gene—will be a crucial determinant of success (see Section 11.6). Recall that continued expression of a mutant driver gene is generally critical to ongoing tumor growth and therefore cannot be shut down by cancer cells as an immunoevasive maneuver without incurring the cost of reducing their fitness. In contrast, cancer cells can indeed shut down expression of a mutant passenger gene without paying a fitness price in terms of their own proliferation or survival, thereby evading further immune attack and resulting in the rebound of a tumor's growth.

OceanofPDF.com

Glossary

time to progression

The period between inception of a treatment and the subsequent progression of a tumor under treatment to a stage of worse clinical presentation or higher stage of malignancy.

OceanofPDF.com

16.4 Passive immunization with antibodies can be used to treat cancer

The immunotherapeutic strategies described above are focused on energizing the immune system to deploy its humoral and cellular arms to attack targeted tumor cells. An alternative and often more productive strategy is to provide a patient with antibody molecules that have been formed outside the patient's body, that is, to supplement or replace limited endogenous immune responses by providing cellular agents or immune molecules that arise elsewhere. (In fact, a form of passive immunization operates naturally during gestation, when the immune system of the developing fetus is augmented by maternal antibodies acquired via placental transfer; similarly, in the first postnatal years, the immune systems of the very young are strengthened and diversified by antibodies supplied via maternal milk.)

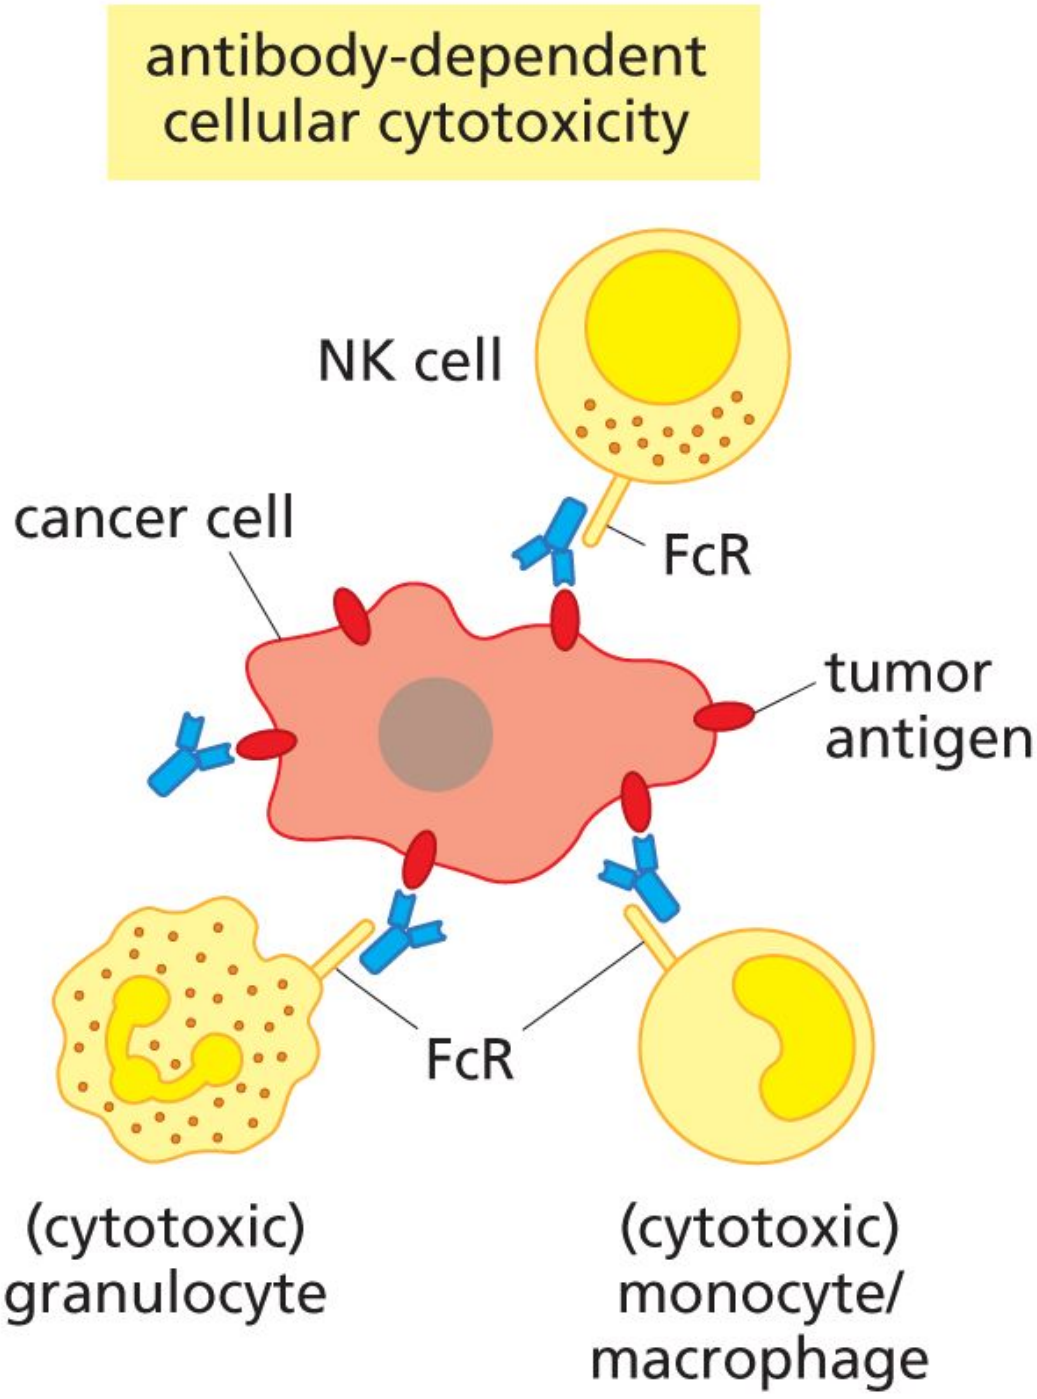
To date, antibody-based passive immunization technologies have yielded the most successful and diverse immunotherapies. The power of antibody-mediated attacks on cancer cells derives from the specificity and high affinity of antigen–antibody reactions and the many weeks-long persistence of introduced antibodies in a patient's circulation.

The advent of technologies for the manufacture of monoclonal antibodies (moAbs) has made the generation of homogeneous populations of antibody molecules routine (**Supplementary Sidebar 16.1**). Unlike the heterogeneous mixtures of antibodies generated during the natural immune response, solutions of moAbs contain antibodies that are, at the molecular level, identical to one another. Moreover, moAb technology makes it possible to generate antibodies of virtually any desired specificity. Equally important, recombinant DNA technology has enabled the reengineering of antibody molecules, making them substantially more effective and versatile, even creating, as we will see, highly useful antibody-like molecules that do not occur in nature.

In more detail, the use of therapeutic moAbs offers two alternative strategies for attacking cancer cells. Some antibodies exert their anti-tumor activity directly by binding to tumor cells and killing them or, more commonly, impairing their further proliferation. Others act indirectly by modifying the behavior of components of the tumor microenvironment in ways that lead to the impairment or death of tumor cells. Thus, such indirectly acting moAbs may target certain cells or factors that are essential for tumor survival and progression without targeting the tumor cells themselves.

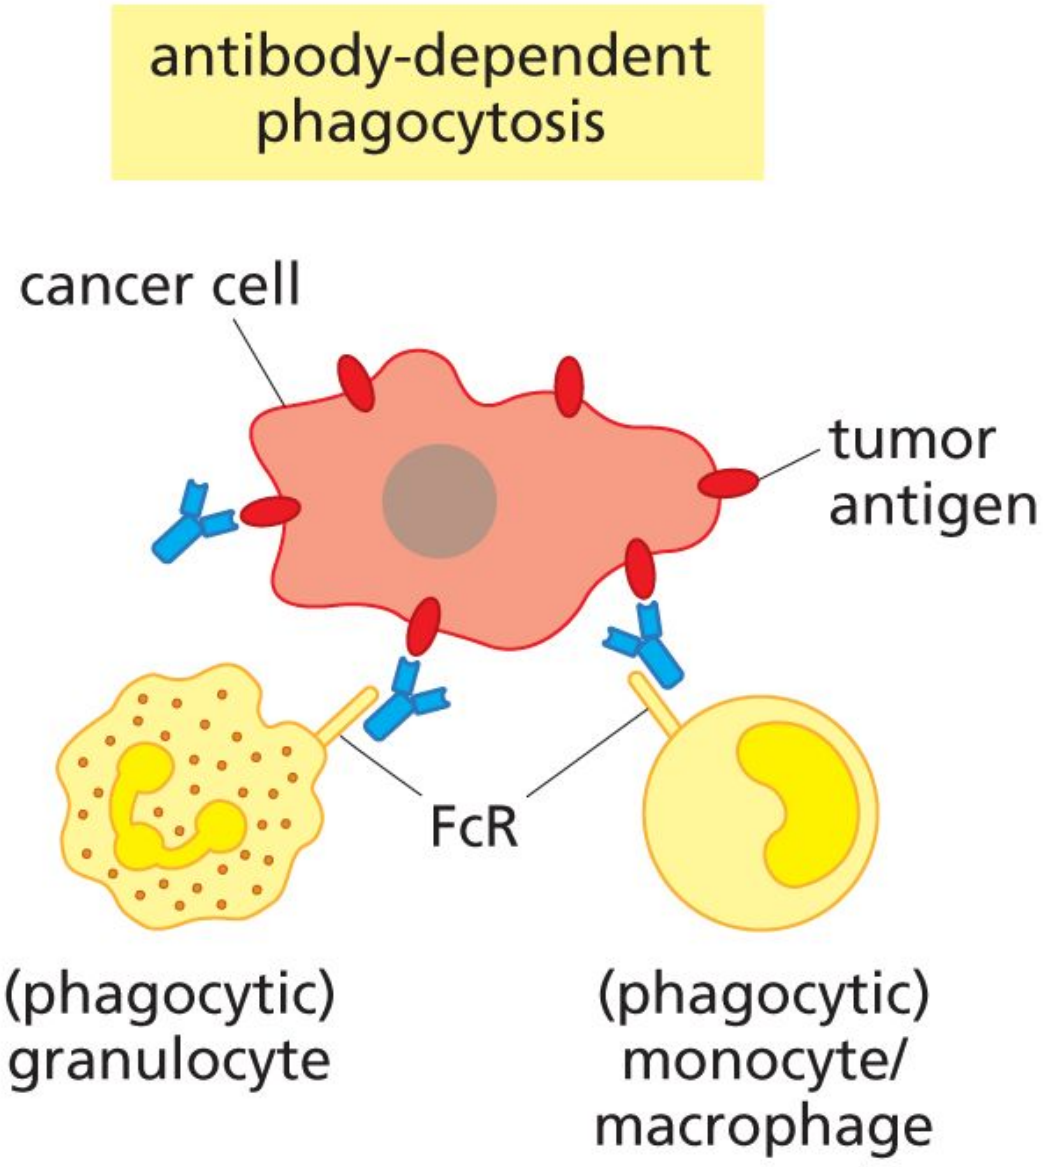
There are actually five distinct ways in which antibodies, such as moAbs, can bind directly to antigens displayed on the surface of targeted cancer cells and thereafter provoke the death of these cells. In all these strategies, the critical antigens are displayed directly on the plasma membrane rather than being presented by the MHC-I/II molecules described in Section 15.6.

Several of these treatments involve recruitment of cellular agents of the innate immune system that can recognize cell-bound antibody molecules, doing so by recognizing the Fc constant region of the already-bound antibody molecules. Such Fc-dependent attacks arise because cellular components of the innate immune system, specifically natural killer (NK) cells, macrophages, and neutrophils, naturally display Fc receptors (FcRs), which specifically recognize and bind to the Fc regions of certain subclasses of immunoglobulin gamma (IgG) molecules that have previously bound to the surfaces of cells. Once these cell-bound IgG molecules are recognized and bound by any one of these three classes of innate immune cells (via the various FcRs displayed by these cells), the process termed antibody-dependent cellular toxicity (ADCC) is triggered and the targeted cells, in our case cancer cells, are killed by the cytotoxic powers of the attacking immune cells (**Figure 16.4A**).



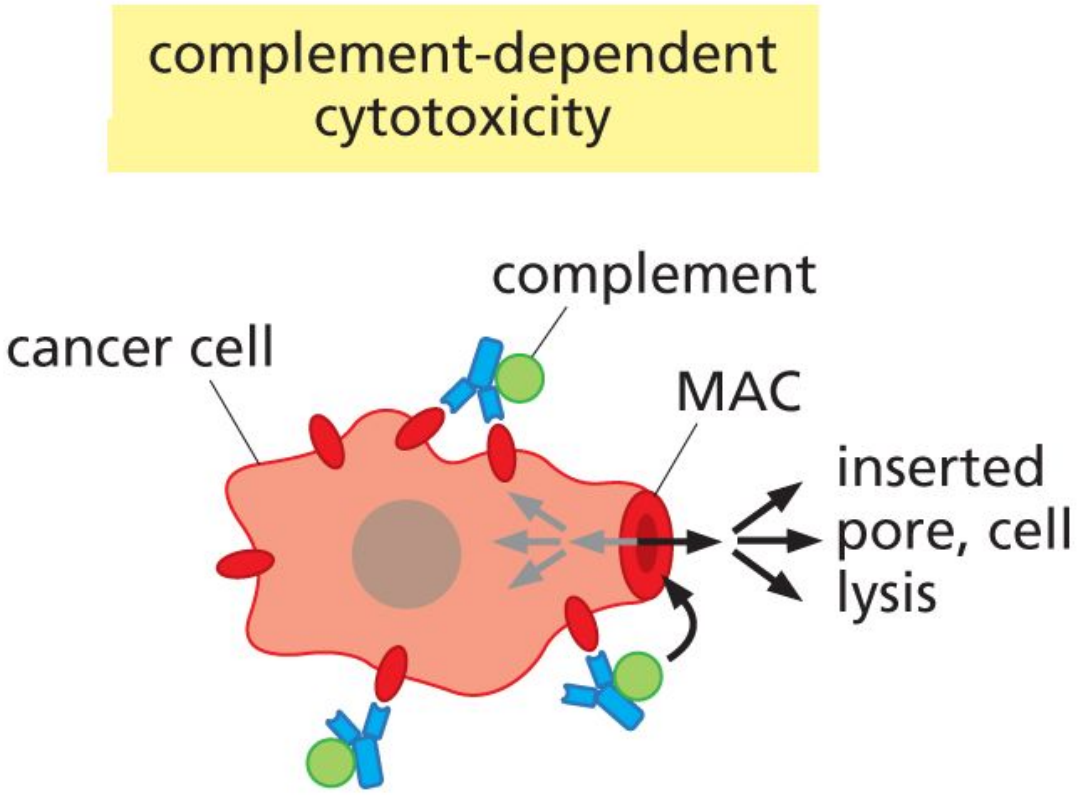
Antibody-dependent cellular cytotoxicity. The cancer cell is attacked by a natural killer cell, a cytotoxic granulocyte, and a cytotoxic monocyte slash macrophage, each of which has an F c receptor that has bound to an antibody attached to a cancer cell antigen.

(A)



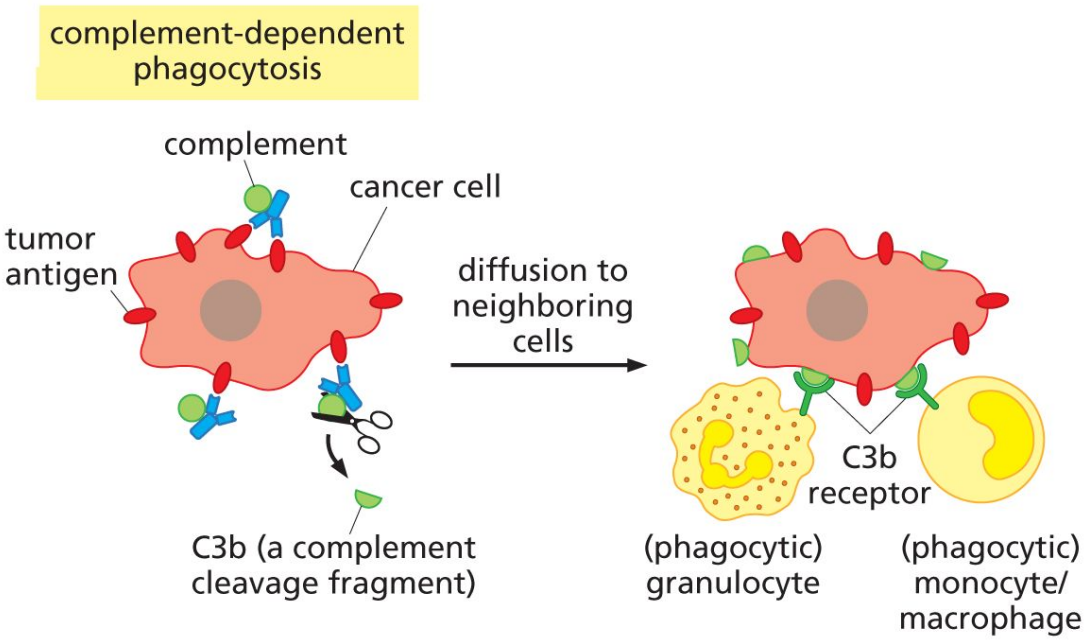
Antibody-dependent phagocytosis. The cancer cell is attacked by a phagocytic granulocyte and a phagocytic monocyte slash macrophage, each of which has an F c receptor that has bound to an antibody attached to a cancer cell antigen.

(B)



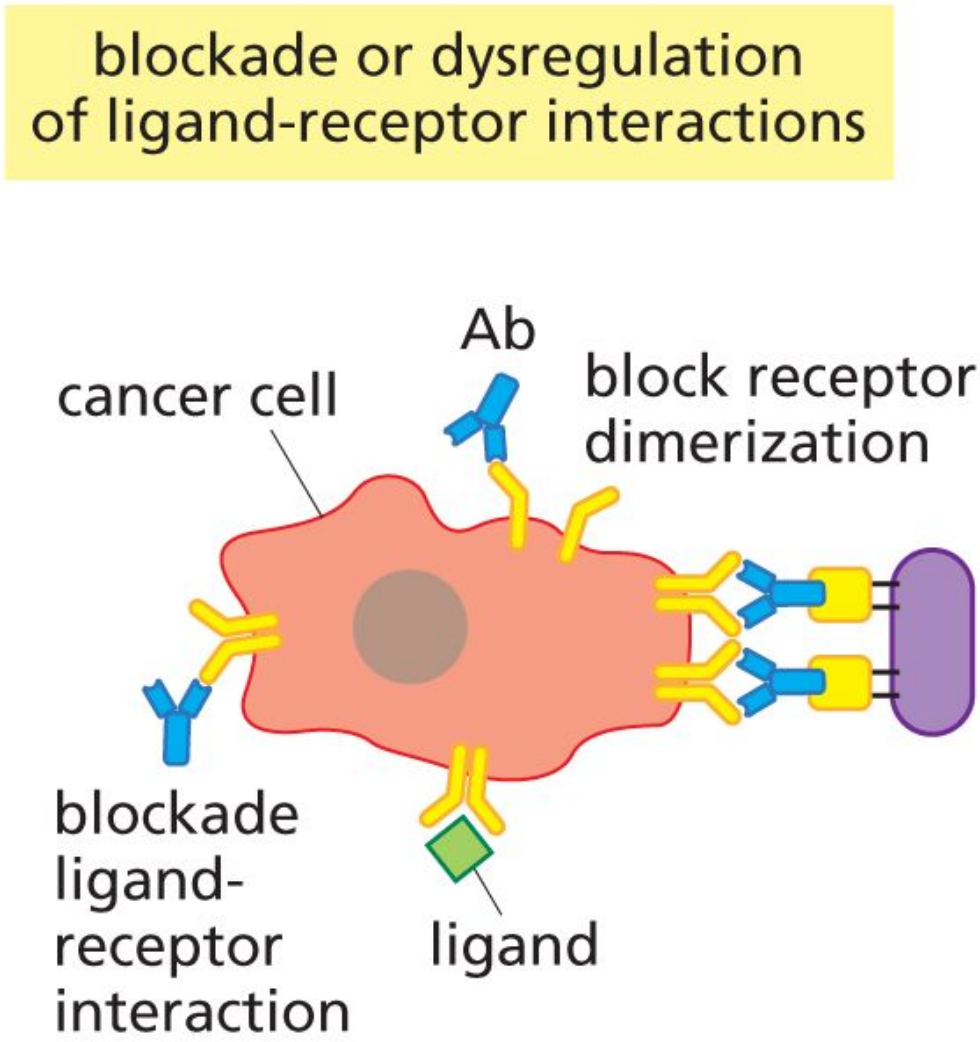
Complement-dependent cytotoxicity. Complement proteins attach to the antibodies bound to the cancer cell. The complement proteins form membrane attack complexes that insert pores into the cell membrane, resulting in cell lysis.

(C)



Complement-dependent phagocytosis. Complement proteins attach to the antibodies bound to the cancer cell. C 3 b fragments are cleaved off the complement proteins and attach elsewhere on the cancer cell. The cancer cell is then shown being attacked by a phagocytic granulocyte and a phagocytic monocyte slash macrophage, each of which has a C 3 b receptor.

(D)



Blockade or dysregulation of ligand-receptor interactions. Ligands that normally bind to dimerizing receptors on the cancer cell are blocked from doing so by the presence of antigen molecules that bind to the receptors.

(E)

Figure 16.4 Multiple distinct mechanisms of cancer cell killing by antibodies and complement The binding of antibody molecules to cell surface antigens expressed by targeted cancer cells affords multiple alternatives routes of attack by the immune system. (A) Antibody-dependent cellular cytotoxicity (ADCC). Binding of tumor antigen-reactive antibodies to surface-displayed tumor antigens is followed by recognition of the Fc regions of the bound antibodies via Fc receptors displayed by phagocytes and NK cells, triggering their killing of the targeted cell. (B) Antibody-dependent phagocytosis (ADP). Engagement of the Fc regions of antibodies bound to tumor cells with the Fc receptors of phagocytes

induces phagocytosis of tumor cells. (C) Complement-dependent cytotoxicity (CDC). Interaction of complement with the Fc region of tumor cell-bound antibodies triggers the assembly of complement-derived components, collectively known as the membrane attack complex (MAC), on the surface of the tumor cell, which punches holes in its plasma membrane (*right*), allowing the free exchange of ions and soluble molecules between the cell interior and the external milieu, leading in turn rapidly to cell death. (D) Complement-dependent phagocytosis (CDP). An alternative response occurs after the activated antibody:complement complex has bound to a cell surface antigen: one subunit of the complement complex may be cleaved, yielding C3b, a polypeptide fragment of a key complement component subunit. Once formed, C3b can be deposited on sites near its site of generation including the surfaces of neighboring cells. Any cells decorated with these C3b fragments can then recognized by C3b receptors on phagocytes and engulfed. (E) Blockade or dysregulation of ligand–receptor interactions. Interference with receipt by the targeted cancer cell of essential growth or survival signals, leading to induction of apoptotic signaling or prevention of receptor dimerization, also resulting in cell death. (A–C, E adapted from G.J. Weiner, *Nat. Rev. Cancer* 15:361–370, 2015.)

A second, related strategy of attack can be mounted by macrophages and neutrophils, both of these being phagocytes whose engagement with the Fc regions of cell-bound IgG molecules results in the engulfment via phagocytosis of antibody-tagged cells (Figure 16.4B).

Yet a third type of lethality is dealt by the activation of the complement system, a group of soluble plasma proteins that can be activated by antibodies bound to cells, causing the death of target cells in either of two ways. In one mode of antigen-directed cell killing, the protein components of the complement system recognize and bind cell-bound antibody molecules (once again recognizing the Fc portion of the bound antibody). The resulting multi-subunit protein assemblies create pore-forming complexes, that is, complexes of proteins that insert pores into the adjacent plasma membrane of the cell under attack. Such pores, once formed, deal a death blow to the targeted cell, because they prevent the cell from maintaining its normal osmotic gradients and thus its viability, doing so by allowing various low–molecular-weight substances, notably ions, to flow freely into and out of the cytoplasm. Such a pore-forming assembly of proteins is known as the membrane attack complex (MAC) (Figure 16.4C).

A fourth mechanism of antibody-mediated cell killing is also complement dependent. The instigating C3b protein is a by-product of the activation of complement by its interaction with antigen–antibody complexes (see Figure 16.4D), such as those formed between anti-tumor antibodies and cell surface tumor antigens. Complement activation

proceeds by proteolytic cleavage, a reaction triggered by antigen–antibody complexes, that results in the formation of a number of cleavage products, including C3b. Following their generation, these C3b proteins, which are highly hydrophobic, diffuse to a nearby cell and bind to its plasma membrane in a fashion that is completely nonspecific. Now membrane-bound, C3b attracts the attention of C3b receptor-bearing macrophages and other phagocytes, such as neutrophils, prompting their phagocytosis of cells decorated with this complement-derived protein fragment (Figure 16.4D). Notably, this avenue of complement-mediated cell killing has the potential to kill nearby tumor cells as well, because cytotoxic components of the activated complex can diffuse from their sites of formation and eliminate these bystanders. Even nearby members of the tumor population that may have contrived to lose expression of the tumor antigen targeted by the antibody will be subject to bystander killing.

A fifth mechanism of antibody attack involves interference at the cell surface with receptor–ligand interactions employed by the cancer cells, usually interactions that are required by cancer cells to drive their own continued proliferation or ensure their survival (Figure 16.4E). The actions of growth factor ligands and their cognate receptors come to mind here, as was described in Chapter 5. The antibody-mediated interference may take any one of a number of forms, including sequestration of a vital ligand on which a cancer cell depends, blockade of ligand binding by the receptor, and even receptor binding that triggers the release of aberrant signals that cause cell death.

OceanofPDF.com

Glossary

Fc receptor
: A cell surface protein displayed by immunocytes, such as NK cells, dendritic cells and macrophages, that recognizes and binds the constant regions of antibody molecules, notably IgG molecules, the latter being bound via their variable regions to antigens on the surfaces of potential target cells such as microbes or cancer cells; such binding enables killing of the antibody-bound cells by the NK cells or macrophages.

membrane attack complex
: The complex of multiple proteins including cell surface–bound antibody molecules and complement proteins that can introduce pores in the nearby plasma membrane, thereby killing an involved cell.

complement
: Group of collaborating plasma proteins that can associate with antibody molecules bound to cell surface antigens, such as antigens displayed by bacterial, yeast, or mammalian cells; once attached via these antibody molecules to a cell surface, complement can kill the cell by introducing pores into the nearby cell membrane, including the plasma membrane of mammalian cells.

16.5 Lymphoma and breast cancer can be treated with monoclonal antibodies

The cell surface glycoprotein CD20 is characteristically expressed by cells at multiple stages of normal B-cell differentiation and rarely on T cells. This limited range of expression made it an attractive target for antibody-mediated attack on non-Hodgkin's lymphomas, 85% of which derive from cells of the B-cell lineage and display this antigen. A genetically engineered monoclonal antibody, termed rituximab (**Sidebar 16.3**), with binding specificity for CD20, was generated for the treatment of this cancer (**Sidebar 16.4**). It became the first moAb approved for cancer therapy, having gained FDA approval for clinical use in 1997 and being widely employed thereafter for the treatment of certain types of relapsed or refractory B-cell lymphoma.

Sidebar 16.3 The conventions for naming monoclonal antibodies are systematic but complex

A complex set of naming conventions has been adopted to name monoclonal antibodies, each of which carries one name reflecting use of these conventions and a second name by which it may be marketed. For example, trastuzumab is the technical name of the antibody molecule marketed as Herceptin^{TM}.

The "mab" suffix refers to a monoclonal antibody, while the first syllable, for example, the "tras" in trastuzumab, has no particular meaning and is given to confer a unique identity. The "tu" in trastuzumab refers to reactivity with a tumor antigen, while the "zu" syllable refers to a *humanized* monoclonal antibody (see Sidebar 16.4). The "xi" syllable indicates a chimeric antibody in which the constant region sequences are human and most or all of the variable region sequences are nonhuman. As an example, in rituximab, working backward, "mab" indicates monoclonal antibody, "xi" denotes chimeric origin, "tu" indicates targeting of a tumor antigen, and "ri" is the individual unique identifying prefix of this antibody that lacks further meaning. Additional, highly specialized syllables, not listed here, indicate yet other properties of a given moAb.

Sidebar 16.4 Devising useful monoclonal antibodies is a complex process

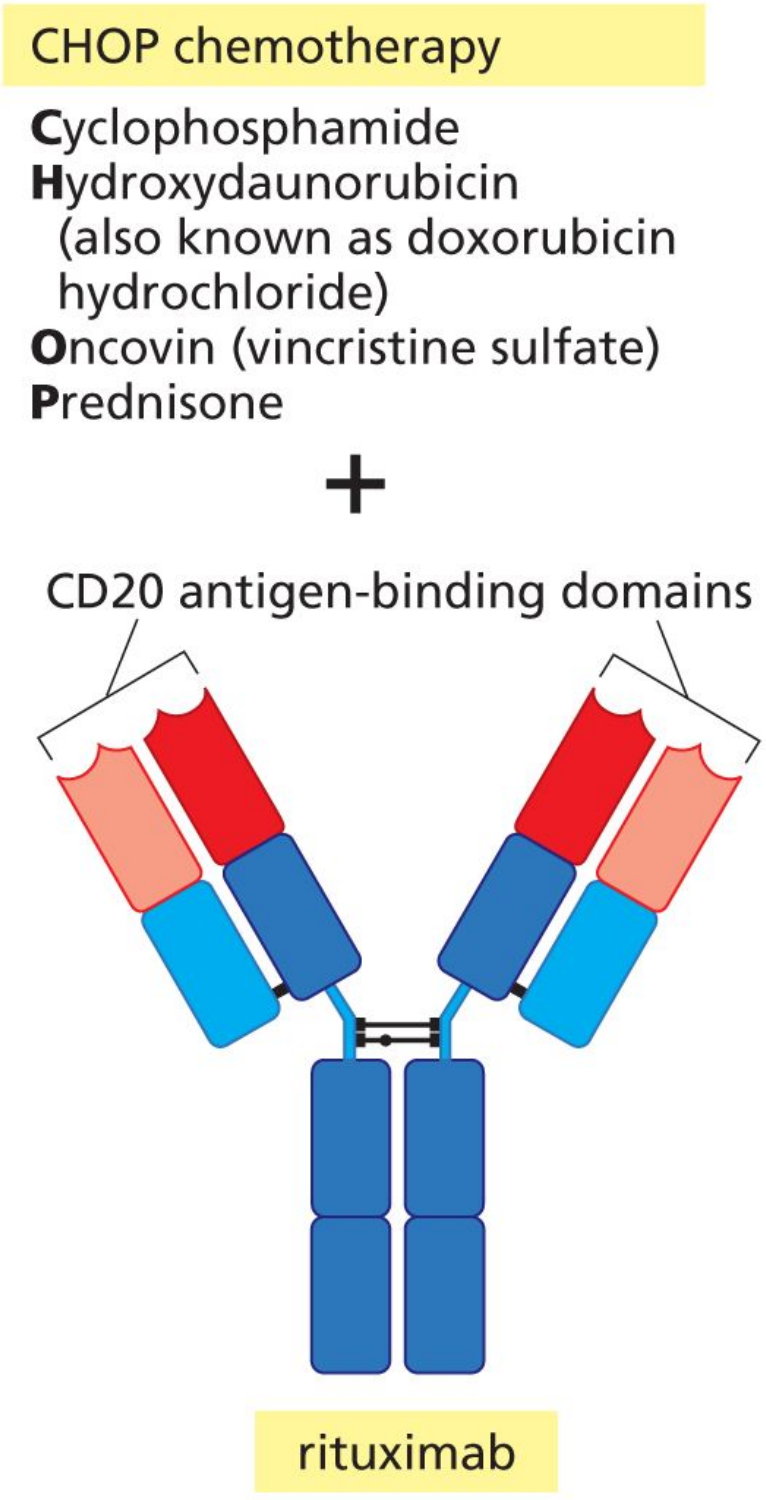
Monoclonal antibodies (mAbs) were initially derived by immunizing mice with antigens of interest, such as cancer cell-associated proteins, deriving moAb-producing cells of mouse origin (see **Supplementary Sidebar 16.1**), and introducing the secreted mAbs, as a form of passive immunization, into the circulation of patients being treated for various conditions. These early treatments made it apparent that such antibodies can have exquisite antigen specificity, being able to bind to targeted antigens while ignoring the tens of thousands of other proteins made in the body. However, their usefulness was often reduced because the supplied mAb molecules were themselves immunogenic, being of mouse origin and displaying amino acid sequences and conformations that directly induced human anti-mouse antibody (HAMA) responses by the immune systems of the patients under treatment. Once a patient's immune system developed HAMA reactivity, the introduced mouse mAb became useless because HAMA neutralized the response.

The problem of reactivity against intact mouse moAbs was largely addressed by genetic engineering, in which portions of the immunogenic constant regions of mouse-derived mAb molecules were replaced by corresponding human segments. This maneuver produced chimeric antibodies, that is, ones in which the large sections of mouse constant region were replaced by their human equivalents but retained the variable regions of the mouse antibody; such antibody molecules preserved the antigen specificity of the original mouse antibody derived from its variable regions. These "chimeric" antibody molecules typically contain about 30% of murine antigen-binding sequences together with about 70% of human amino acid sequences, while even more extensively altered "humanized" moAbs have eliminated almost all mouse sequences, retaining only those forming the antigen-binding sites of murine origin. However, as explained in **Supplementary Sidebar 16.1**, technologies now exist for the derivation of fully human antibodies of any desired specificity. Indeed, most of the moAbs currently being developed for clinical use are formed by entirely human amino acid sequences.

Rituximab was first introduced into clinical practice to treat diffuse large B-cell lymphoma (DLBCL), a prevalent form of non-Hodgkin's lymphoma. At the time of its introduction, DLBCL was usually treated with the chemotherapy protocol known as CHOP (a combination of the cytotoxic drugs **c**yclophosphamide, **h**ydroxydoxorubicin, **o**ncovin (vincristine sulfate), and **p**rednisone). Among its other limitations, the use of CHOP in elderly patients was constrained because dose escalation could not be undertaken due to the severity of side effects experienced in this population.

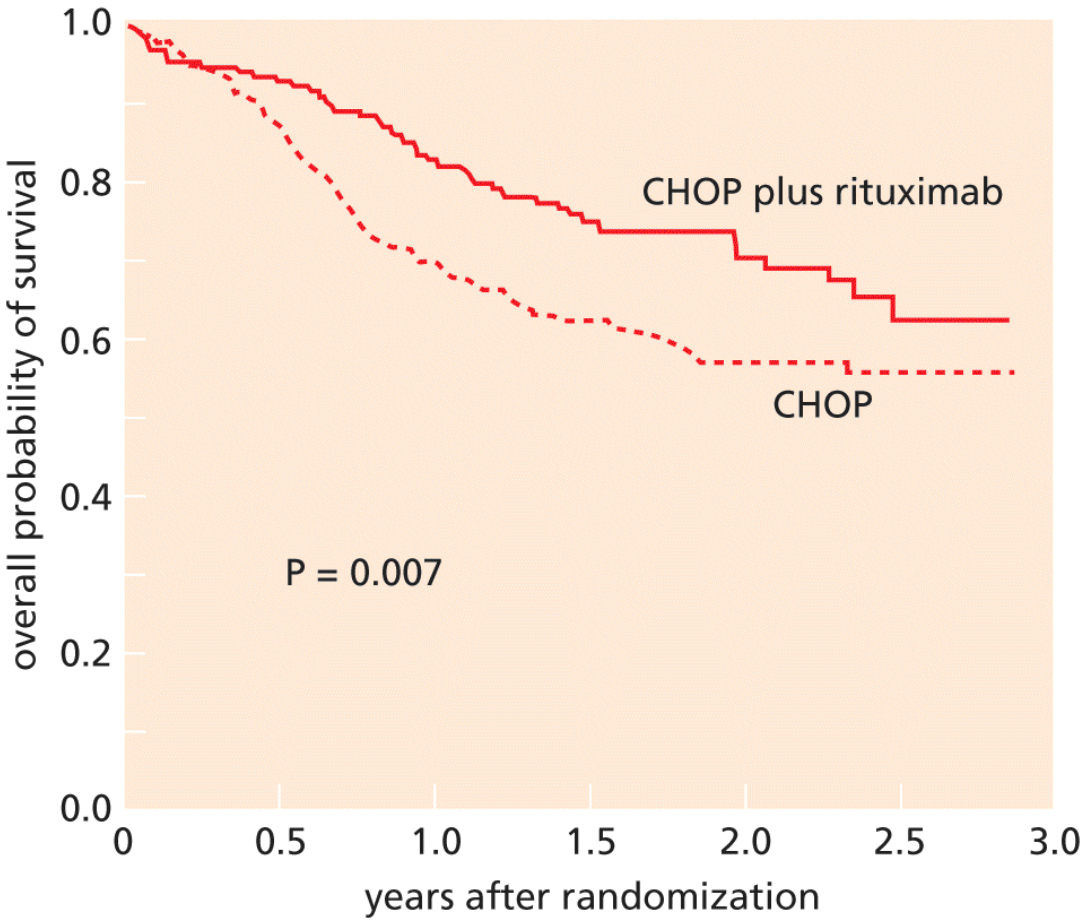
A clinical trial that compared treatment of elderly DLBCL patients with CHOP alone or CHOP plus rituximab showed that adding rituximab to standard CHOP chemotherapy significantly improved event-free survival and prolonged overall survival compared to treatment with CHOP alone (**Figure 16.5**). More generally, as

clinical experience with moAb therapies has grown, it has become apparent that, like their chemotherapeutic forerunners, these agents are usually more effective as components of combination therapies than when they are employed as stand-alone monotherapies.



CHOP chemotherapy combines Cyclophosphamide, Hydroxydaunorubicin (also known as doxorubicin hydrochloride), Oncovin (also known as vincristine sulfate), and Prednisone. It may be combined with the engineered antibody rituximab, which has C D 20 antigen-binding domains.

(A)



A line chart showing the overall probability of survival as a function of time for two groups of patients. Of the patients given CHOP without rituximab, a little more than 60 percent remained alive 1.5 years after randomization. Of the patients given CHOP with rituximab, about 75 percent remained alive 1.5 years after randomization. The difference diminished in later years. Of the patients given CHOP without rituximab, a little less than 60 percent remained alive 3 years after randomization. Of the patients given CHOP with rituximab, a little more than 60 percent remained alive 3 years after randomization.

(B)

Figure 16.5 Combination therapy with anti-tumor antibody and chemotherapy (A) CHOP therapy directed toward B-cell–derived lymphomas involves a combination of cytotoxic compounds and rituximab, an anti-CD20 monoclonal antibody. (B) Overall survival among elderly patients (median age, 69 years) with diffuse large B-cell lymphoma (DLBCL) treated with CHOP or CHOP plus rituximab. (B, from B. Coiffier, E. Lepage, J. Briere et al., *N. Engl. J. Med.* 346:235–242, 2002. With permission from Massachusetts Medical Society.)

Monoclonal antibodies have also had a substantial impact on the immunotherapy of a subset of breast cancers. As a prominent example, as many as 15 to 20% of human mammary carcinomas overexpress human epidermal growth factor receptor-2 (HER2), the close cousin and signaling partner of the EGF receptor (see Sections 4.2 and 5.3). When its expression is elevated in breast cancer cells, this receptor molecule serves as a tumor-associated antigen that can be targeted by anti-HER2 antibodies. In fact, it serves as more than a tumor cell-associated antigen target, because various studies have demonstrated that overexpression of HER2 provides critical mitogenic and anti-apoptotic signals to breast cancer cells.

Trastuzumab, an anti-HER2 humanized monoclonal antibody, was the first successful antibody-based therapy for breast cancer and showed efficacy in prolonging progression-free and overall survival in patients with HER2-positive breast cancer. Studies of the mechanisms responsible for the anti-tumor effects of trastuzumab, also termed Herceptin, showed that its use led to attacks on HER2-positive cancer cells via multiple mechanisms, including recruitment of innate immune cells by antibody-dependent cellular cytotoxicity (ADCC), induction of complement-dependent cellular cytotoxicity (CDCC), and interference with growth factor signaling. Overall, in a meta-analysis that included the clinical histories of 13,864 breast cancer patients over the course of a decade, when applied together with chemotherapy, trastuzumab treatment reduced patient mortality by 33% relative to treatment with chemotherapy alone, a significant advance by any standard.

More recently, alternative versions of anti-HER2 mAbs have been generated and deployed in the cancer clinic. One of these, termed pertuzumab, targets a distinct domain of the HER2 protein and prevents its heterodimerization with HER3 (another EGFR-related receptor protein), thereby blocking HER2 signaling. Its distinct mechanism-of-action explains why it functions synergistically with trastuzumab in treating a variety of breast cancer subtypes (**Sidebar 16.5**). In early-stage breast cancers, this combination of moAbs often generates pathological complete responses, that is, the elimination of all cancerous tissue from the site of treatment, including comparable effects on draining lymph nodes (see Figure 14.36), judged in both cases by histopathological assessment. Such responses are often, but not always, indicative of cures.

Sidebar 16.5 The peculiarities of HER2 function limit the efficacy of trastuzumab alone

A key feature of HER2 signaling is its requirement for dimerization with another member of the family of receptor tyrosine kinases (see Section 5.6). As it turns out, a HER2 receptor molecule can dimerize with another HER2 receptor molecule or, alternatively with either HER1 (=EGFR) or HER3, a closely related member of this receptor family. Trastuzumab interferes with the formation of HER2–HER2 homodimers, but it does not block the formation of HER2–HER3 heterodimers, which represent the active signaling complexes following binding of EGF-like ligands. (Trastuzumab fails to block heterodimer formation because it binds to a site on the HER2 molecule that is distinct from the site involved in interaction with HER3.) This failure to block HER2–HER3 heterodimer formation therefore provides an escape pathway for cancer cells under attack by trastuzumab. The development of pertuzumab —the mAb that blocks the formation of HER2–HER3 heterodimers—closed this escape hatch. The complementary action of trastuzumab and pertuzumab was found to be more effective than either antibody alone, and when the trastuzumab–pertuzumab couple was paired with the powerful anti-mitotic agent, docetaxel, a therapy for HER2-positive metastatic breast cancer emerged that became, for a time, the standard of care, especially for HER2-positive metastatic breast cancer. While this combination was surely a milestone in the management of this disease, resistance to this therapy did eventually emerge in a number of patients.

Glossary

dose escalation
: The practice of progressively increasing the dosage of a drug in an investigatory clinical trial in order to determine efficacy of the drug under study at various applied doses and, at the same time, revealing the toxicity of such doses in order define the maximum tolerated dose. *See also* **maximum tolerated dose.**

meta-analysis
: Statistical procedure for pooling and integrating the results of a number of independent experimental, clinical, or epidemiologic studies in order to generate a larger data set and greater statistical significance than is afforded by the data of only a single study.

pathological complete response
: The response of a tumor to a therapy that involves the complete elimination of microscopically detectable remnants of a tumor under treatment. *See* **complete response**.

standard of care
: The therapeutic agent or protocol that is widely accepted in the treatment of disease and often serves as the reference against which candidate novel treatments are measured.

16.6 Antibody–drug conjugates deliver toxic drugs to cells displaying tumor antigens

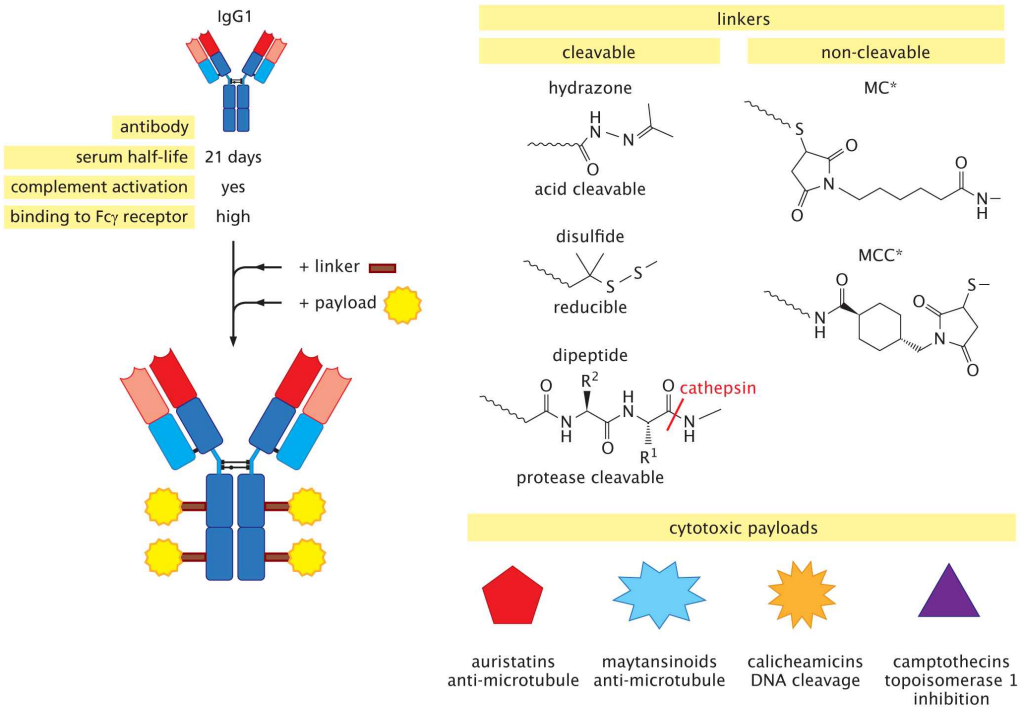
The highly specific targeting afforded by anti-tumor mAbs can be exploited to direct a variety of cytotoxic drugs to the relatively small number of tumor cells in the body, thereby sparing the normal cells and tissues elsewhere in the body. By doing so, such antibody–drug conjugates (ADCs) address a major limitation of existing cytotoxic chemotherapies, that of limited therapeutic index (TI), which represents the ratio of the concentration at which a drug generates unacceptable side-effect toxicities to the concentration at which it creates desired therapeutic responses; high TIs are desirable because they reflect the specificity with which various agents act preferentially on intended targets, including tumors, without creating major side effects.

Chemical coupling with toxic molecules can also greatly enhance the cytotoxic effects of the antibody molecules. These responses ensue when the antibody–drug conjugates are internalized by antibody-bound cells. In most instances, the antibody portions of the ADCs should ideally retain many of the functions of unmodified moAb molecules, including the ability of cell-bound antibodies to trigger lethal attacks by antibody-dependent cellular cytotoxicity (ADCC), antibody-dependent phagocytosis (ADP), and complement dependent cellular cytoxicity (CDCC). Similarly, those moAb molecules that disrupt or perturb ligand–receptor signaling should, in most cases, retain this ability following their conjugation with cytotoxic drug molecules.

In more detail, each ADC is formed from three components, an antibody molecule against a tumor antigen, a highly potent cytotoxic drug molecule, and a molecular linker between the two. Stringent requirements are placed on the cytotoxic drug and on the linker. Because relatively small numbers of the cytotoxic drug molecules are actually delivered into individual targeted cells, the intrinsic cytotoxicity of the drug must be very high, explaining why such agents, when used as unmodified soluble molecules, often exert toxicity in the subnanomolar-to-picomolar concentration range.

The linker must be stable in the bloodstream, allowing the antibody to retain its cargo until it binds to and is internalized by a targeted cell. Without this stability, ADCs can release their toxic payload molecules directly into the bloodstream, causing off-target toxicity to normal tissues—precisely the outcome that ADCs were invented to avoid. However, once internalized by a targeted cell, the cytotoxic payload must be released through cleavage from the linker or by the intracellular digestion of the ADC, liberating in either case biologically active drug moieties. As shown in **Figure 16.6**, a great many permutations of the theme of antibody, linker, and cytotoxic drug payload are possible. Most ADCs are built on a human IgG1 backbone, a subclass of antibody molecules that, in unmodified form, enjoy a long

serum half-life of 21 days. Their Fc region should be able to trigger complement activation and, because they represent a ligand for binding by the Fc receptors of NK cells, macrophages, and neutrophils, should also enable target cell killing by these innate immune cells.



The Construction of an antibody drug conjugate. It begins with an I g G 1 subclass antibody, with a serum half life of 21 days. There is complement activation and high binding to an F c gamma receptor. Four payloads are connected to the F c portion, two on each side. Each payload is connected by a linker element. Linkers may be cleavable, such as hydrazone, which is acid-cleavable; disulfide, which is reducible; and dipeptide, which is protease cleavable. Linkers may also be non-cleavable, such as M C star and M C C star. Cytotoxic payloads include auristatins, which are anti-microtubule; maytansinoids, which are also anti-microtubule; calicheamicins, which engage in D N A cleavage; and camptothecins, which engage in topoisomerase 1 inhibition.

Figure 16.6 Construction of an antibody–drug conjugate Antibody molecules, usually of the IgG1 subclass, are used because they have a long half-life and their Fc regions are bound by Fc receptors displayed by phagocytes and NK cells. These antibody molecules are modified by the covalent attachment of highly toxic drug molecules referred to as “payloads.” A variety of cleavable linkers, five of which are shown here (*right*), are used to conjugate toxic payload molecules to antibody molecules. The figure shows the four major classes of chemical species currently used as cytotoxic payloads (*lower right*). (Adapted from J.Z. Drago, S. Modi and S. Chandarlapaty, *Nat. Rev. Clin. Oncol.* 18:327–344, 2021. With permission from Nature.)

ADCs often offer additional benefits. Leakage of the introduced toxic molecules from cells directly targeted by an ADC may result in the killing of additional tumor cells present in the nearby tissue microenvironment, acting by the so-called bystander effect. This ideally offers the benefits of killing neighboring tumor cells that may have escaped targeting by the ADC, either by chance or because they have adopted evasive strategies including down-regulation of a targeted tumor antigen. Antibody–drug conjugates constitute a rapidly expanding category of cancer drugs and several have received FDA approval for the treatment of a broad range of cancers (**Table 16.2**).

Table 16.2 Antibody–drug conjugates approved for clinical use

ADC	Target antigen	moAb isotype	Payload	Payload class	Payload action	Drug-to-antibody ratio (DAR)	Disease indication (year of approval)
Gemtuzumab ozogamicin	CD33	IgG4	Ozogamicin	Calicheamicin	DNA cleavage	2–3	$CD33^+$ R/R AML (2000)[a]
Brentuximab Vedotin	CD30	IgG1	MMAE	Auristatin	microtubule inhibitor	4	R/R sALCL or cHL (2011) R/R pcALCL or $CD30^+$ MF (2017) cHL, sALCL or $CD30^+$ PTCL (2018)[b]
Ado-trastuzumab emtansine (T-DM1)	HER2	IgG1	DM1	Maytansinoid	microtubule inhibitor	3.5 (mean)	advanced-stage $HER2^+$ breast cancer previously treated with trastuzumab and a taxane (2013); early stage $HER2^+$ breast cancer in patients with residual

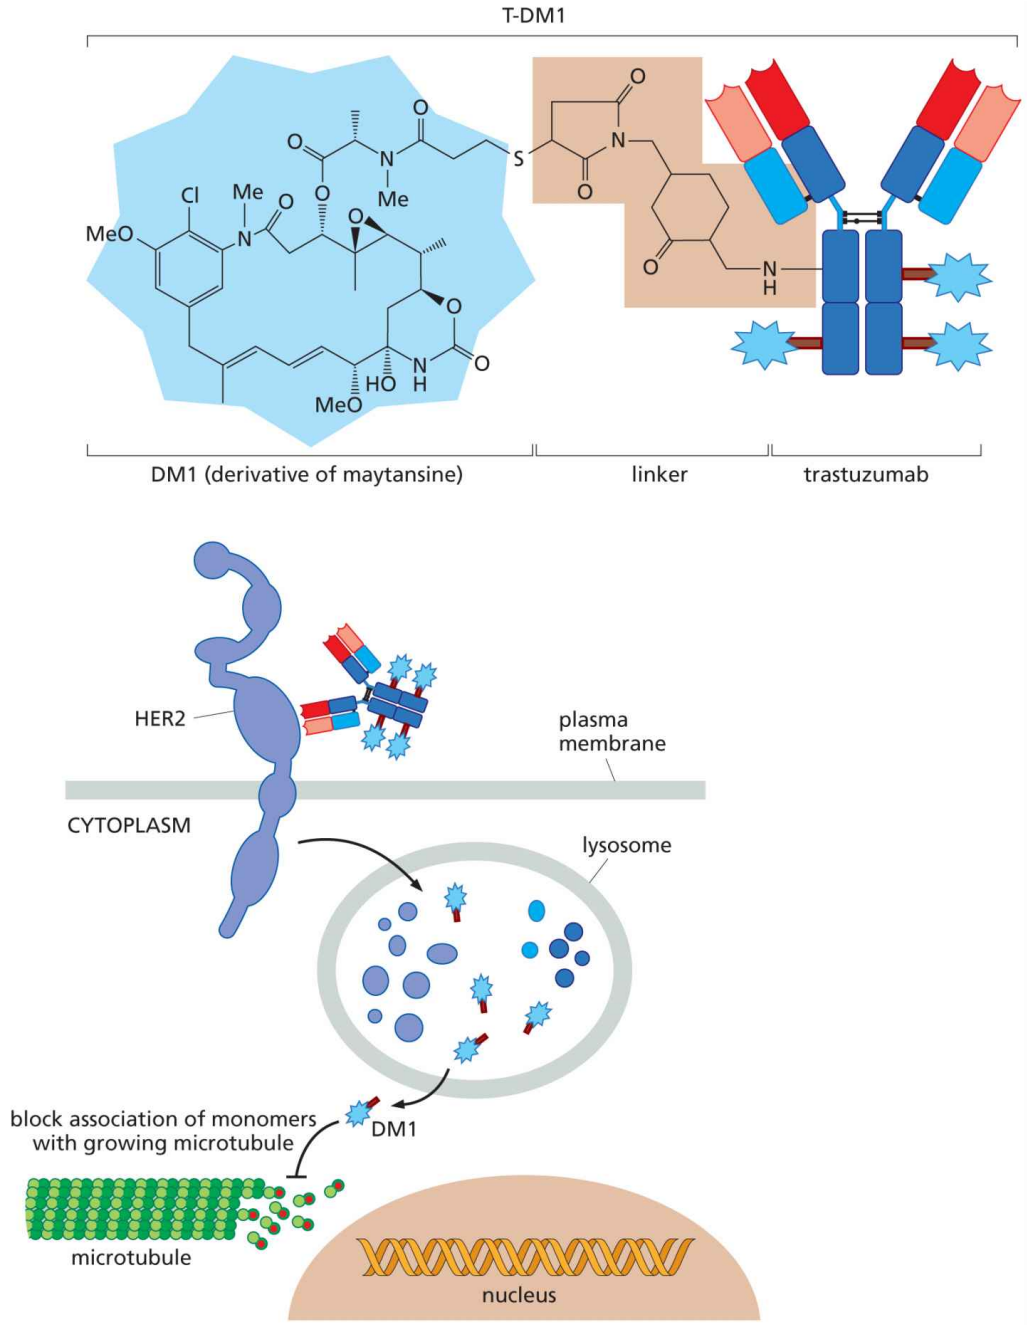
ADC	Target antigen	moAb isotype	Payload	Payload class	Payload action	Drug-to-antibody ratio (DAR)	Disease indication (year of approval)
							disease after neoadjuvant trastuzumab–taxane- based treatment (2019)
Inotuzumab ozogamicin	CD22	IgG4	Ozogamicin	Calicheamicin	DNA cleavage	5–7	R/R B-ALL (2017)
Fam-trastuzumab deruxtecan-nxki (T-DXd)	HER2	IgG1	DXd	Camptothecin	TOPO1 inhibitor	8	advanced-stage $HER2^{+}$ breast cancer after two or more anti-HER2-based regimens (2019)
Polatuzumab vedotin-piiq	CD79b	IgG1	MMAE	Auristatin	microtubule inhibitor	3.5 (mean)	R/R DLBCL (2019)[c]
Sacituzumab govitecan-hziy	Trop-2	IgG1	SN-38 (active metabolite of irinotecan)	Camptothecin	TOPO1 inhibitor	8	advanced-stage, triple-negative breast cancer in the third-line setting or beyond (2020)
Enfortumab vedotin-ejfv	Nectin 4	IgG1	MMAE	Auristatin	microtubule inhibitor	4	advanced-stage urothelial carcinoma,

ADC	Target antigen	moAb isotype	Payload	Payload class	Payload action	Drug-to-antibody ratio (DAR)	Disease indication (year of approval)
							following progression on a PD-1 or PD-L1 inhibitor plus platinum-containing chemotherapy (2020)
Belantamab mafodotin-blmf	BCMA	IgG1	MMAF	Auristatin	microtubule inhibitor	unknown	R/R multiple myeloma in the fifth-line setting or beyond (2020)

ADC, antibody–drug conjugate; AML, acute myeloid leukemia; B-ALL, B-cell acute lymphoblastic leukemia; BCMA, B-cell maturation antigen; cHL, classical Hodgkin's lymphoma; DLBCL, diffuse large B-cell lymphoma; moAb, monoclonal antibody; MF, mycosis fungoides; MMAE, monomethyl auristatin E; MMAF, monomethyl auristatin F; pcALCL, primary cutaneous anaplastic large-cell lymphoma; PTCL, peripheral T-cell lymphoma; R/R, relapsed and/or refractory; sALCL, systemic anaplastic large-cell lymphoma; TOPO1, topoisomerase I; Trop-2, tumor-associated calcium signal transducer 2. Adapted from Z.J. Drago, S. Modi and S. Chandarlapaty, *Nat. Rev. Clin. Oncol.* 18:327–334, 2021. With permission from Nature.

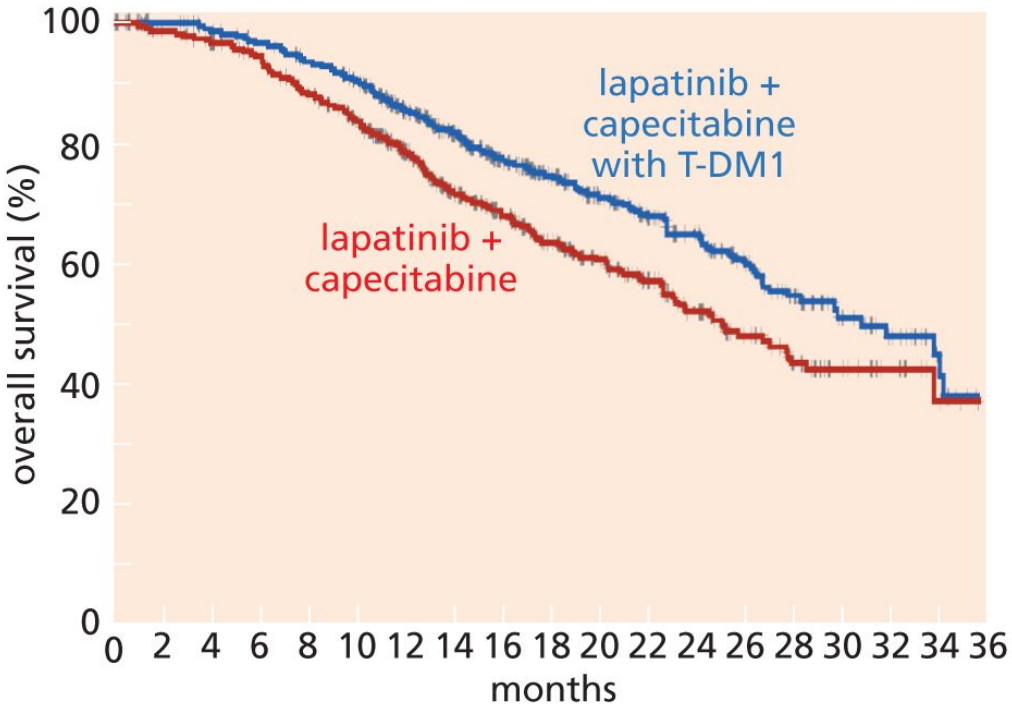
As an example, trastuzumab emtansine, an ADC derivative of trastuzumab, targets cells that express HER2, doing so via the trastuzumab moiety of the conjugate; after binding, this ADC delivers DM1, a highly cytotoxic microtubule inhibitor to the HER2-expressing cell. In addition to its role in the delivery of a cytotoxic payload, the antibody retains most of the preexisting potent anti-tumor properties associated with the parental moAb (**Figure 16.7A**). Compared to a standard chemotherapy for patients who had been previously treated with a combination of trastuzumab and a taxane (another class of small–molecular-weight microtubule inhibitors), the ADC provided significant gains in overall survival (Figure 16.7B). Furthermore, these gains were achieved with less toxicity than experienced with lapatinib and capecitabine, two low–molecular-weight cytotoxic drugs that are often used in

combination in patients whose tumors have escaped trastuzumab and taxane-mediated chemotherapy.



The structure of the antibody drug conjugate T-D M 1. It consists of the antibody trastuzumab, a linker, and the maytansine derivative D M 1 as the payload. The mechanism of action is that the antibody's receptor domains bind to an H E R 2 protein protruding from the surface of a cancer cell. The D M 1 molecules make their way into a lysosome, and from there move to block microtubule growth by blocking the association of monomers with growing microtubules.

(A)



A line chart showing the overall probability of survival as a function of time for two groups of patients. Of patients treated with lapatinib and capecitabine alone, 60 percent survived to 20 months. Of patients treated with lapatinib and capecitabine and also T- D M 1, 70 percent survived to 20 months. Just under 40 percent of either group survived to 35 months.

(B)

Figure 16.7 Use of an antibody–drug conjugate (ADC) to treat breast cancer (A) The cytotoxic drug DM1, a chemical derivative of the potent microtubule inhibitor, maytansine (*above left*), is chemically coupled via a thioether linker to one of four alternative sites in the constant region of an anti-HER2 moAb directed against this receptor molecule (*above right*), which is frequently overexpressed in breast cancers. After being administered to a patient afflicted with a HER2-overexpressing breast cancer, the ADC can bind to a HER2 molecule (*purple, lower left*) displayed on the surface of $HER2^+$ cancer cells. The ADC–HER2 complex is then internalized via endocytosis and is thereafter delivered to a lysosome within which the linker is cleaved. This liberates the maytansine moiety, which can then escape the lysosome and enter into the cytosol, where it inhibits the growth of microtubules and therefore the assembly of the mitotic apparatus in the M phase of the cell cycle. (B) The Kaplan–Meier graph presents the results of a clinical trial demonstrating that treatment with the ADC, TDM1 (*blue curve*) produced significant gains in short-term survival compared with a standard chemotherapy (lapatinib-capecitabine, *red curve*) employed with this type of breast cancer, although long-term survival was not significantly affected. (A, Adapted from

P.M. Lorosso, D. Weiss, E. Guardino et al., *Clin. Cancer Res.* 17:6437–6447, 2011. With permission from American Association for Cancer Research. B, from S. Verma, D. Miles, L. Gianni et al., *N. Engl. J. Med.* 367:1783–1791, 2012. With permission from Massachusetts Medical Society.)

Nevertheless, the tumors borne by some patients eventually develop resistance to trastuzumab emtansine. In a number of these patients, this acquired resistance cannot be associated with the shutdown of HER2 antigen expression. Instead, in some of these patients, the observed loss of sensitivity to this ADC can be linked to alterations in lysosomal trafficking and degradation. In others, it is possible that tumor cells develop resistance to the emtansine payload caused by certain changes in intracellular biochemistry. Hence, the mechanisms underlying acquired resistance to trastuzumab emtansine are often poorly understood.

The impact of ADCs on breast cancer extends beyond the set of HER2-positive breast cancers to include triple-negative breast cancers (TNBC). These aggressive cancers, named because they lack readily detectable expression of the estrogen, progesterone, and HER2 receptors, account for around 15% of invasive breast cancers, are more common in younger than older women, and, in the United States, occur with higher frequency in African Americans than in other races and ethnic groups. Sequential single-agent chemotherapy has represented the standard of care and yields low response rates and short periods of progression-free survival.

The absence of HER2 expression by TNBCs guarantees their unresponsiveness to HER2-targeting antibodies and derived ADCs. However, there is a fallback option: the majority of breast cancers (including TNBCs) express human trophoblast cell surface antigen 2 (Trop-2). Accordingly, a humanized moAb specific for Trop-2 has been derived and coupled to a potent topoisomerase I inhibitor, creating the antibody drug conjugate sacituzumab govitecan. In a definitive clinical trial that compared the effects of this ADC with chemotherapy, the median overall survival of patients given sacituzumab govitecan was 12.1 months and thus superior to the 6.7-month median overall survival of patients given chemotherapy instead. These findings demonstrate the superiority of the ADC over chemotherapy with regard to progression-free survival and the potential impact of these different treatments on tumor growth and regression.

16.7 Cancer can be treated by adoptive cell transfer

In the sections above, we encountered a series of immunotherapeutic strategies in which the powers of a patient's immune system were augmented or complemented by agents of foreign origin. In particular, these strategies involved antibodies generated outside the body, modified in some cases, and finally introduced into patients' bodies in order to supplant functions that the immune system of these patients was incapable of generating on its own. An entirely different strategy involves capturing components of a patient's native immune response to a tumor, amplifying them outside the body in ways that do not occur naturally, and introducing these components back into the patient's body. Once again, such strategies are designed to compensate for the inability of a patient's native immune system to mount certain types of effective anti-tumor responses on its own.

As we saw in Chapter 15, T cells are the major governors of immune responses to cancer and therefore are key determinants of whether tumors are eliminated, kept under control, or progress. In fact, diverse studies of tumor histology (see Figures 15.3, 15.4, and 15.5) have revealed that many actively growing tumors harbor significant populations of T cells that coexist with large numbers of neoplastic cells but nonetheless have clearly failed to eliminate the cancer cells.

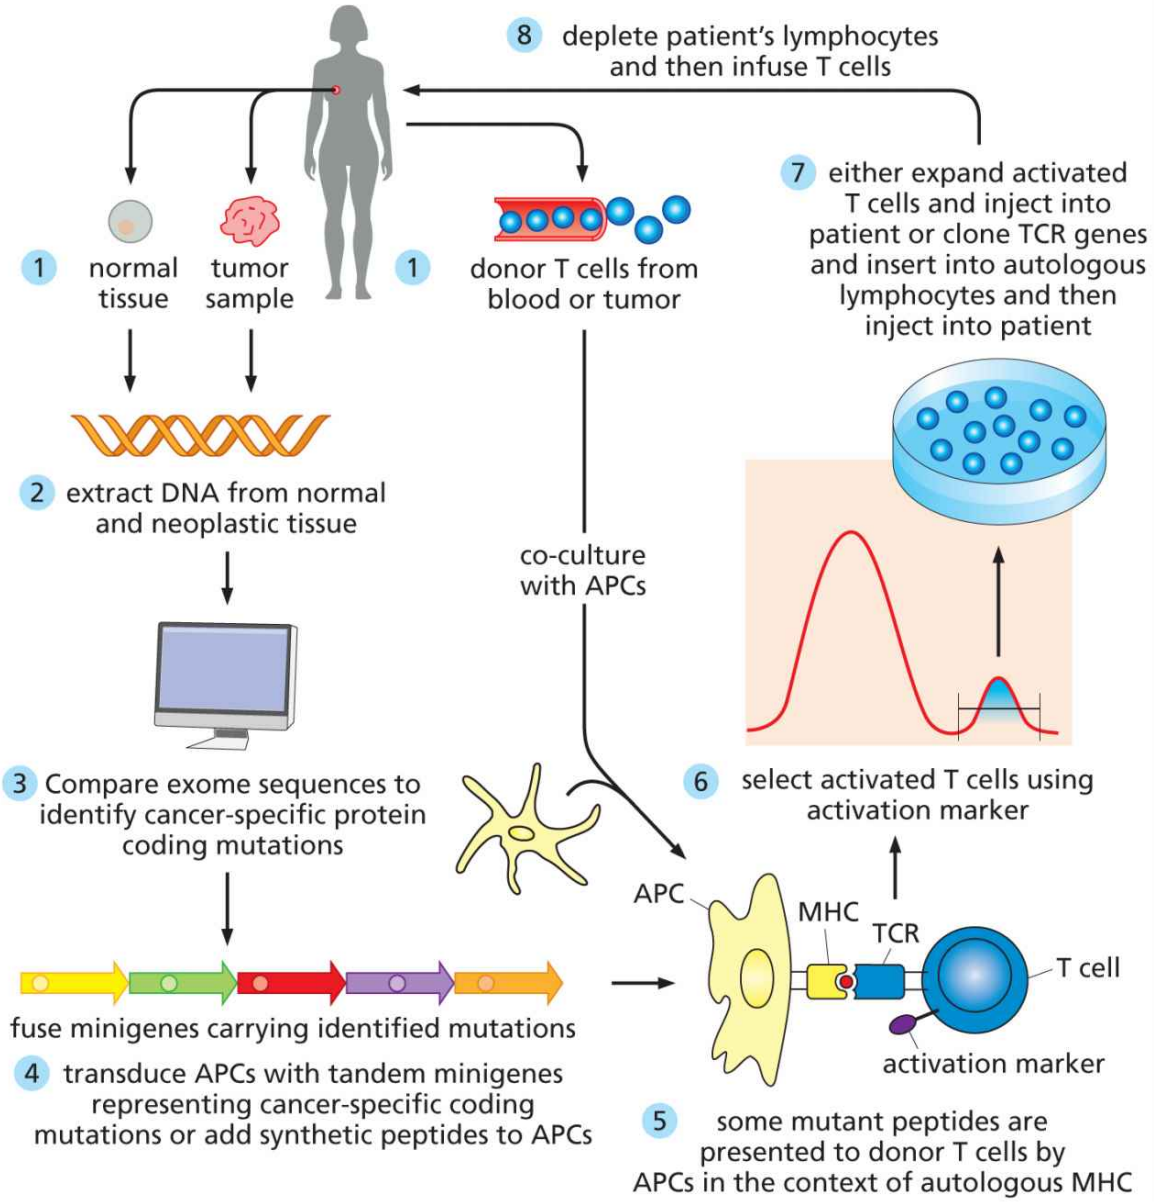
The repeated detection of such tumor-infiltrating T lymphocytes (TILs) has stimulated a major thrust in the development of anti-cancer immunotherapies, which is inspired by the notion that such infiltrating T cells are not present in adequate numbers or in physiological states that would allow them to effectively kill nearby cancer cells. This notion has led to the development of methods for harvesting T cells from a patient, manipulating them *ex vivo,* and then introducing the altered lymphocytes back into the donor or into other histocompatible recipients. Such a clinical strategy, which also represents a form of passive immunization, is termed adoptive cell transfer (ACT).

In adoptive cell transfer, immune cells, almost invariably T cells, are harvested directly from a patient's excised tumor, expanded *ex vivo* into much larger cell populations, and then transferred back into the patient via intravenous infusion. Ideally, among the reintroduced cells are anti-tumor cytotoxic T cells whose

TCRs direct cytotoxic attacks on cells that display tumor-associated antigens, while sparing cells that do not. By necessity, this target specificity was initially developed in the donor's body during the period when the tumor was growing out and provoking various types of adaptive immune responses. Two major versions of ACT T-cell immunotherapies have been developed: adoptive transfer of T cells bearing conventional TCRs and adoptive transfer of T cells bearing chimeric antigen receptor T cells (CAR T cells).

To provide some background, we note that during the last quarter of the twentieth century, various experiments demonstrated that certain subpopulations of T cells could be harvested from tumor-bearing mice and thereafter propagated in culture under conditions that greatly increased their number without these cells losing their critical biological functions. The expansion of these murine T-cell populations *ex vivo* depended on the inclusion in the *in vitro* growth medium of the cytokine interleukin-2 (IL-2), a potent T-cell growth factor. Later, it became possible to expand corresponding human lymphocytes *ex vivo*. In both cases, the expanded lymphocyte populations could be re-infused back into the bodies of the donors that previously formed them (or, more precisely, formed their initially harvested progenitors). These re-introduced T lymphocytes should not be recognized as foreign and therefore should not provoke an immune response that would blunt or eliminate them in the bodies of engrafted recipients.

In more recent versions of this strategy, genomic sequencing is used to identify tumor-specific somatic mutations in the coding sequences of a patient's cancer cell genome (**Figure 16.8**). Once identified, these mutant sequences can be used to construct recombinant "minigenes" that encode oligopeptides carrying the mutant amino acid sequences (rather than encoding the full-length mutant proteins). Moreover, in a single tumor genome, multiple polypeptide sequences, corresponding to various somatic mutations registered in the patient's tumor genome, can be identified; each of these sequences can be used to construct a recombinant minigene, and the resulting collection of minigenes can be linked to one another to create a tandem string of minigenes. (Such mutant tumor cell sequences can derive from somatically mutated driver genes as well as passenger genes because both are equally capable of specifying tumor-specific antigens.)



An Overview of adoptive T-cell transfer cancer therapy. Step 1 is the extraction of normal tissue and tumor tissue samples from a patient. Separately, donor T cells from the patient's blood or the tumor are also extracted and co-cultured with antigen-presenting cells. Step 2 is to extract D N A from the normal and neoplastic tissue samples. Step 3 is to Compare exome sequences to identify cancer-specific protein coding mutations. Step 4 is to transduce antigen-presenting cells with tandem minigenes, representing cancer-specific coding mutations, or to add synthetic peptides to antigen-presenting cells. This is done by fusing together minigenes carrying identified mutations. Step 5 is to present some mutant peptides to cultured donor T cells by antigen-presenting cells in the context of autologous M H C. These T cells

receive an activation marker. Step 6 is to select activated T cells using the activation marker. Step 7 is to either expand activated T cells and inject them into the patient, or to clone T C R genes and insert them into autologous lymphocytes, and then inject these into the patient. Step 8 is to deplete the patient's lymphocytes and then infuse T cells.

Figure 16.8 Overview of adoptive T-cell transfer cancer therapy The schematic outline of this treatment strategy shows the following steps: (1) Samples of normal and tumor tissue are taken from the patient and T cells are obtained from the tumor or from blood (*top left*). (2) DNA is extracted from normal and tumor tissue and is subjected to exomic sequencing. (3) Comparison of the tumor vs. normal exome sequences allows identification of structural mutations, that is, those that encode differences in the amino acid sequences of proteins, leading in turn to identification of candidate tumor-specific neoantigens. (4) Minigenes, each specifying a peptide of 25 amino acids in length flanking and including an identified somatic structural mutation, are synthesized, linked in tandem, and transfected into APCs, enabling expression and presentation of encoded neoantigen peptides by the transfected APCs. Five fused minigenes, each represented by a different color are shown here. Alternatively, neoantigen peptides can be chemically synthesized and added directly to *in vitro* cultures of APCs. The presence of mutations in each of these genes is suggested by the small lighter circles within each. (5) Co-culture of patient T cells harvested in Step 1 allow those APCs displaying neoantigen peptides to activate T cells prepared from the patient (*dark blue*) bearing TCRs that recognize complexes of neoantigen peptide:MHC (*lower right*) presented by mutant oligopeptide-displaying dendritic cell (APC). (6) The minority of T cells that display activation markers after interaction with the peptide-displaying APC are identified by flow cytometry, sorted, and expanded to large numbers ($>10^{10}$) *ex vivo*. (7) The expanded populations of neoantigen-reactive T cells are infused into the donor, who has previously undergone lymphodepletion by treatment with a cytotoxic drug in order to create a niche for the infused cells. (Adapted from S.A. Rosenberg and N.P. Restifo, *Science* 348:62–68, 2015.)

These strings of minigenes can then be processed further to encourage the outgrowth *ex vivo* of specific lymphocyte subpopulations that recognize and respond to them. Thus, DNA molecules carrying these minigenes can be transfected into donor-derived antigen-presenting cells (APCs), which should then permit the APCs to present minigene-encoded mutant peptides on their cell surface MHC-I molecules. In principle, co-culture of these transfected APCs with

the patient's cultured T cells should trigger activation of a subset of the donor's explanted immunocytes, in particular those lymphocytes bearing T-cell receptors (TCRs) specific for the mutant peptide-antigen:MHC complex that had previously been exhibited *in vivo* by the patient's own tumor cells and therefore experienced by the precursors of the explanted T cells. The resulting *in vitro* activated T cells, ideally expanded to far larger numbers, can then be infused back into the patient's body.

Although creative in exploiting our existing knowledge of T-cell biology, these ACT strategies are complicated by certain realities of immune regulation (**Sidebar 16.6**).

Sidebar 16.6 Development of effective ACT strategies requires attention to many complicating factors

In practice, the design of an adoptive cell transfer protocol requires attention to a number of critical biological details. To begin, the APCs used in these APC experiments should ideally come from the patient because the spectrum of MHC molecules that these APCs employ to present oligopeptide antigens should be identical to those used by the patient's tumor cells to do so. This is critical because, as we learned in the last chapter, the complex molecular structures recognized by TCRs are oligopeptide antigens together with the "hands" of the MHC molecules that hold and present these oligopeptide antigens (see Figure 15.7). In addition, the tumoricidal powers of the lymphocyte populations propagated *ex vivo* are greatly strengthened when the minority populations of these lymphocytes that have been successfully activated by exposure to minigene-encoded peptides are harvested for re-infusion into the donor (discarding those lymphocytes that have not been activated). This enrichment can be achieved by harvesting only those lymphocytes that express on their surface certain antigens associated with T-cell activation. As shown in Figure 16.8, such cells can be detected readily in cultured lymphocyte populations, isolated, and further expanded *in vitro,* thereby preparing them for subsequent re-infusion into the donor cancer patient.

Yet another biological detail needs to be respected in order to maximize the success of the ACT re-infusion protocol described here: Prior to T-cell re-infusion, patients need to be treated with cytotoxic chemotherapeutic drugs in order to reduce the populations of resident lymphocytes and other leukocytes in their immune systems, thereby "making room" for the re-infused lymphocytes

and facilitating their taking root in the recipient's body. Following re-infusion of the *ex vivo* expanded lymphocytes, patients are often given IL-2 to help support successful engraftment and proliferation of the re-infused T cells, including the rare T cells that, following infusion, happen to encounter cancer cells displaying the peptide:MHC complexes that they recognize. It is worth noting that because systemic IL-2 can cause toxic side effects, more recent research has focused on innovative T-cell culture protocols that reduce the need for sustained *in vivo* treatment with IL-2.

As shown in **Table 16.3**, ACT has been used for the treatment of several types of cancer including melanoma, lymphomas, and carcinomas, such as urothelial and breast tumors. Adoptive T-cell transfer, as outlined here, leverages the capacity of T cells to discriminate between oligopeptide sequences that differ by as little as a single amino acid residue. Although elegant in concept and powerful in clinical application, major challenges remain to its widespread adoption in oncology clinics.

Table 16.3 Treatment of cancer by adoptive T-cell transfer

Year	Type of cancer	Molecule targeted	Patients	% objective responses	Comment
1998	melanoma	unknown	15	60	The first clinical trial of TILs; responses were observed but of short duration and TILs did not persist.
2002	melanoma	unknown	13	46%	First use of lymphodepletion before cell transfer, responses were of longer

Year	Type of cancer	Molecule targeted	Patients	% objective responses	Comment
					duration and TIL population persisted.
2008	melanoma	NY-ESO-1	9	33%	First demonstration of feasibility of treating cancer with *in vitro* generated antigen-specific TILs.
2011	melanoma	unknown	93	56%	20% of the patients had complete recoveries exceeding 5 years.
2014	cervical cancer	unknown	9	33%	Treatment of carcinoma with TIL therapy.
2014	cholangial carcinoma	mutated ERB2	1	—	Use of *in vitro* selected antigen-specific TILs to effect complete regression >6 years.

Year	Type of cancer	Molecule targeted	Patients	% objective responses	Comment
2016	metastatic colorectal cancer	mutant KRAS (G12D mutation)	1	—	Use of *in vitro* selected antigen-specific TILs to effect complete regression >5 years.
2018	chemotherapy-resistant metastatic breast cancer	mutant forms of four proteins: SLC3A2 KIAA0368 CADPS2 CTSB	1	—	Use of multiple *in vitro* antigen-specific TIL populations to effect durable regression.

Adapted in part from S.A. Rosenberg and N.P. Restifo, *Science* 348:62–68, 2015.

To begin, as described above, this type of immunotherapy is highly personalized, that is, tailored specifically to the somatic mutations borne by each patient's tumor. It is also extremely labor intensive and requires the resources and a spectrum of medical expertise found only in large academic medical centers to manage its administration and respond to possible side effects.

Also, as summarized in the next section, the biology of conventional T cells and the mechanisms leading to their activation create significant obstacles to widespread adoption in oncology clinics. Hence, the ACT therapy described here, as documented in Table 16.3, has been applied to a variety of cancers. At present, it can be regarded as providing a dramatic demonstration of the powers of the adaptive immune system, but nevertheless remains a therapeutic protocol whose logistics and incurred expense keep it from being introduced into the oncology clinic as a routinely employed strategy in the foreseeable future.

Glossary

adoptive transfer
: Procedure in which immune cells are transferred from a donor to a recipient, undertaken with the goal that the donor’s cells will be able to mediate an immune function in the recipient.

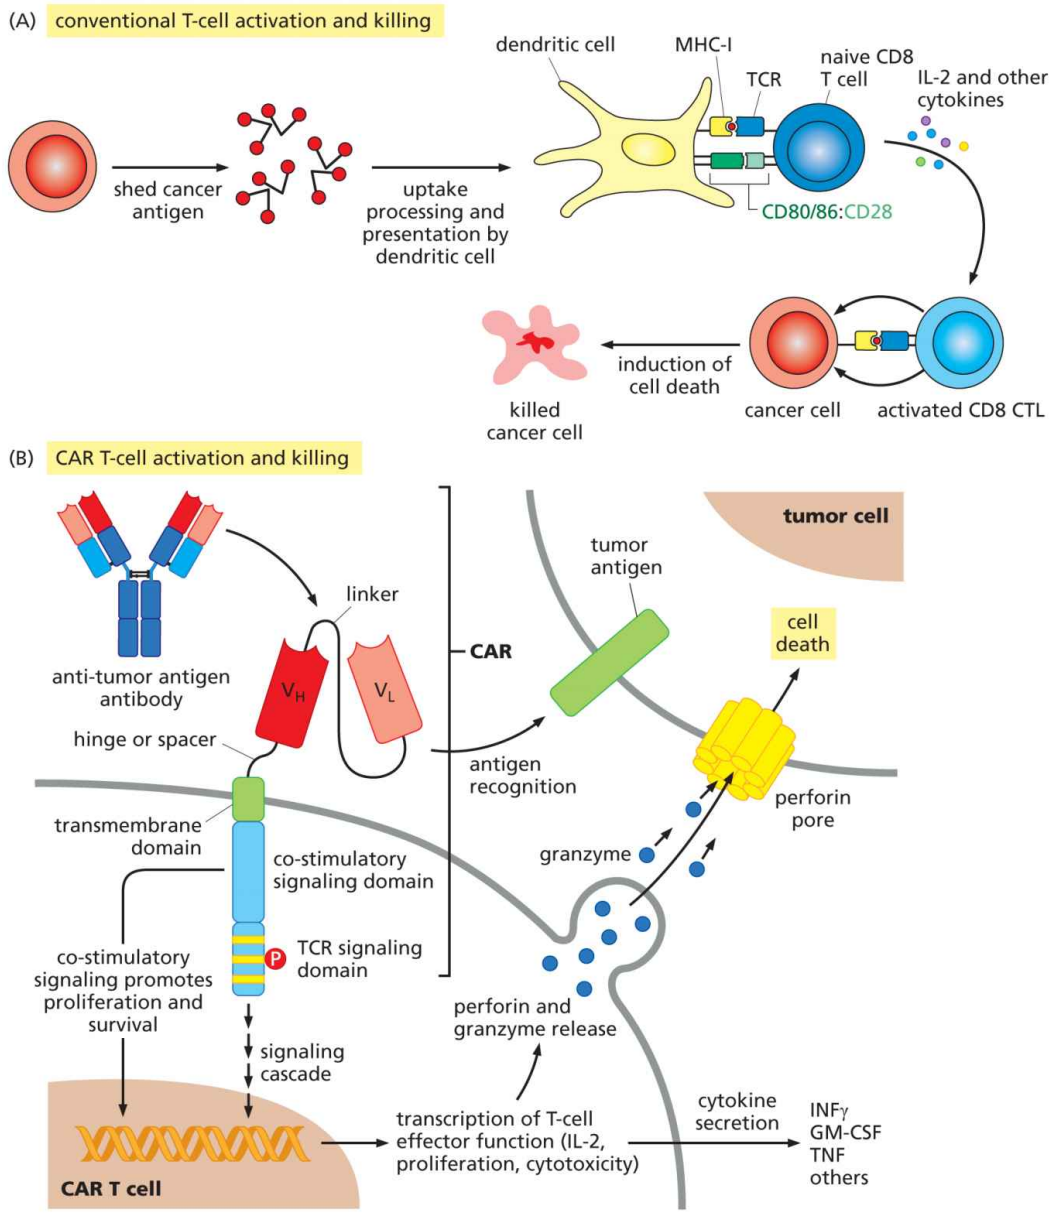
OceanofPDF.com

16.8 CAR T cells have predetermined specificity and bypass MHC-dependent antigen presentation

An alternative adoptive cell transfer strategy involves the modification of T cells in ways that are simpler than the complex, challenging experimental protocol described above. Recall from Section 15.7 that the conventional T-cell activation triggered by APCs occurs in a lymphoid tissue, and requires both antigen recognition by the TCR complex and co-stimulatory signals generated by the T cell's co-stimulatory receptors. The latter must recognize ligands displayed on the surface of antigen-presenting APCs in order for this activation to proceed to completion.

These two recognition events, mediated by the two sets of receptors, trigger a complex set of signaling events within the naive T cell, with each receptor type acting on a largely distinct intracellular signal-transducing circuitry; the resulting signaling events, operating together, result in activation of the T cell.

Subsequently, following its migration out of lymphoid tissues to peripheral, non-lymphoid sites in the body, the activated T cell may encounter cells displaying peptide:MHC complexes recognized by its TCRs; this T cell will then be induced to respond, specifically by launching a cytotoxic attack on the encountered target cells. This complex process, involving multiple different cell types and several distinct receptor–ligand interactions, is outlined in **Figure 16.9A**.



A two-part figure giving an Overview of C A R T-cell biology. Part A depicts conventional T-cell activation and killing. A cancer cell sheds antigens. These undergo uptake processing by a dendritic cell, which then presents them to a naive C D 8 T cell. In the presence of I L-2 and other cytokines, the T cell matures into an activated C D 8 cytotoxic T lymphocyte. This attaches to a cancer cell, inducing the death of the latter. Part B depicts C A R T-cell activation and killing. Upon recognition of a cancer cell antigen, a V H and a V L from an anti-tumor antigen antibody detach and are joined end to end by a linker. The V H attaches via a hinge or spacer to a transmembrane domain on a C A R T-cell, which in turn is attached to a co-stimulatory signaling domain in the cytoplasm, which in turn is attached to a T C R signaling domain. The signaling domain initiates a signaling cascade, and at the same time signaling from the co-stimulatory signaling domain promotes proliferation and

survival. The combined effect is the transcription of T-cell effector function (I L-2, proliferation, cytotoxicity). This results in the secretion of cytokines: interferon gamma, G M-C S F, tumor necrosis factor, and others. The other result is the release, through the plasma membrane, of perforin and granzyme. A perforin pore is formed in the plasma membrane of the cancer cell, and granzymes pass through the pore into the cancer cell's interior, where they cause cell death.

Figure 16.9 Overview of CAR T-cell biology (A) Conventional T-cell activation and killing involves at least three cell types: CD8 T cells (*dark blue*), dendritic cells (*yellow*), and cancer cells (*light red*), the last being the source of tumor antigens for activating T cells and the target of killing. Ligand–receptor interactions between naive T cells and dendritic cells include both TCR recognition of complexes of peptide antigen (*dark red*) formed with MHC-I molecules displayed by dendritic cells and co-stimulation of T cells via C80/86:CD28 interactions. In the presence of IL-2 and other cytokines, these several interactions enable the activation of a naive CD8 T cell (*dark blue*) and its maturation to a functional cytotoxic T lymphocyte (CTL, *light blue*). The resulting activated CD8 T cell can proceed to kill a cancer cell (*light red*) that displays the MHC-I:peptide complex recognized by the T cell's TCR. (B) Chimeric antigen receptor-displaying T-cell (CAR T-cell) responses require only two cell types, a CAR T cell (*lower left*) and its target cell, specifically a tumor antigen-displaying cancer cell (*upper right*). The recognition of the tumor antigen (*green*) on the surface of the target cell is the only type of receptor–ligand interaction required to trigger killing of the targeted cancer cell. Most chimeric antigen receptors include three modules: (1) an extracellular antigen-binding domain comprised of a single-chain variable region fragment (scFv) derived from the V_H and V_L domains of a monoclonal antibody molecule known to bind specifically to a target antigen (*red*, *pink*), (2) a hinge or spacer segment and a short transmembrane domain derived from any of a variety of cell surface receptor molecules (*light green*), and (3) a cytoplasmic domain assembled from two distinct intracellular signaling domains, one providing co-stimulatory signals usually released by a CD28 co-stimulatory receptor (*light blue*) and a domain containing the TCR signaling domain that is usually activated when a TCR recognizes and binds a cognate antigen on a second cell (*blue, yellow stripes*). Engagement of the CAR with the targeted tumor antigen has three major effects: a perforin–granzyme-mediated cytolytic attack by the CAR T cell on the tumor cell (*upper right*), secretion by the CAR T cell of a variety of cytokines (*lower right*), and proliferation and survival of the CAR T-cell population. (Adapted in part from R.J. Lee, J.S. Abramson and R.A. Goldsby, *Case Studies in Cancer*, New York: W.W. Norton, 2019, p. 275, and in part from R.C. Larson and M.V. Maus, *Nat. Rev. Cancer* 21:145–161, 2021. With permission from Nature.)

The general strategy of chimeric antigen receptor (CAR) T-cell therapies bypasses the complexity of this conventional T-cell activation process. These therapies do so by endowing T cells with receptors that enable them to recognize and attack target cells

displaying an already-identified cell surface antigen. This is achieved without identifying and assembling the usually required antigen-specific TCR and its associated co-receptor.

To begin, DNA segments encoding the variable (V) antigen-recognizing domains of certain moAbs can be appropriated as starting points. These mAbs have previously been isolated because they recognize known cell surface antigens displayed by cancer cells. Using recombinant DNA, the two V-encoding DNA segments of such a mAb are isolated and strung together, thereby assembling a gene encoding an entirely artificial antigen-binding receptor. This resulting antigen-binding domain can then be incorporated into a larger protein that carries the additional domains associated with a TCR, specifically the transmembrane domains and the cytoplasmic domains of a TCR; finally, the cytoplasmic domain of a co-stimulatory receptor is added. Hence, the antigen-binding ectodomain of the engineered receptor should mimic the functions of a naturally arising TCR.

If constructed properly (**Sidebar 16.7**), the cytoplasmic domains of this newly constructed receptor should enable the release into lymphocytes of the mixture of biochemical signals that normally occurs when a natural TCR recognizes and binds a cognate antigen. Recall that this binding usually elicits functional activation of the lymphocytes and enables them to kill the cells displaying targeted tumor antigens (Figure 16.9B). (The term “chimeric” in chimeric antigen receptor, CAR, comes from the fact that the antigen-recognizing portion of this artificial receptor derives from an already-identified monoclonal antibody, whereas the transmembrane and cytoplasmic domains derive from the signal-emitting domains of a bona fide TCR plus its companion co-stimulatory receptor, such as CD28 or 4-1BB.)

Sidebar 16.7 T-cell chimeric antigen receptors incorporate functional domains from several different molecules

(1)The process of constructing a chimeric antigen receptor begins with the identification of an antigen that is either tumor associated or tumor specific and is reliably displayed by many, if not all, of the neoplastic cells within a tumor. A suitable mAb is then derived against the identified tumor antigen. The DNA sequences that encode the antigen-binding heavy- and light-chain variable regions of the antibody molecule are then subcloned and linked together via a linker-encoding segment into a single reading frame. This yields an expression construct specifying the antigen-binding domain of the parental moAb from which these sequences were derived. Hence, the antigen-recognizing and -binding functions usually achieved collaboratively by the heavy and light chains of a conventional immunoglobulin are now mediated by a single polypeptide, often termed a single-chain variable region fragment (scFv). (2) This gene construct is then extended further by adding a segment encoding a membrane-spanning polypeptide, often mirroring the transmembrane sequence of a T-cell protein such as the CD8 co-receptor. This polypeptide segment serves the dual functions of connecting the scFv ectodomain to the CAR’s cytoplasmic signaling domains and, at the same time, operates as a molecular hinge, providing flexibility to the scFv ectodomain module of the CAR. (3) This gene fusion is followed by adding a segment encoding the cytoplasmic domain of the CAR that

incorporates the signal-emitting domain of the TCR complex together with the signaling domain of a stimulatory co-receptor molecule, yielding a combined cytoplasmic domain that releases both types of signals into the T-cell cytoplasm following antigen binding.

Ideally, binding of the antibody-derived receptor portion of the CAR by the targeted antigen initiates many of the same T-cell-activating signaling cascades that are triggered within a T cell by engagement of its native TCR. Signals from the co-stimulatory domain contribute to the rate of cell proliferation, the persistence of the CAR T cells, and the durability of the response. As might be apparent, CAR T cells may also kill normal host cells that happen to express the same antigen as the targeted tumor-associated antigen.

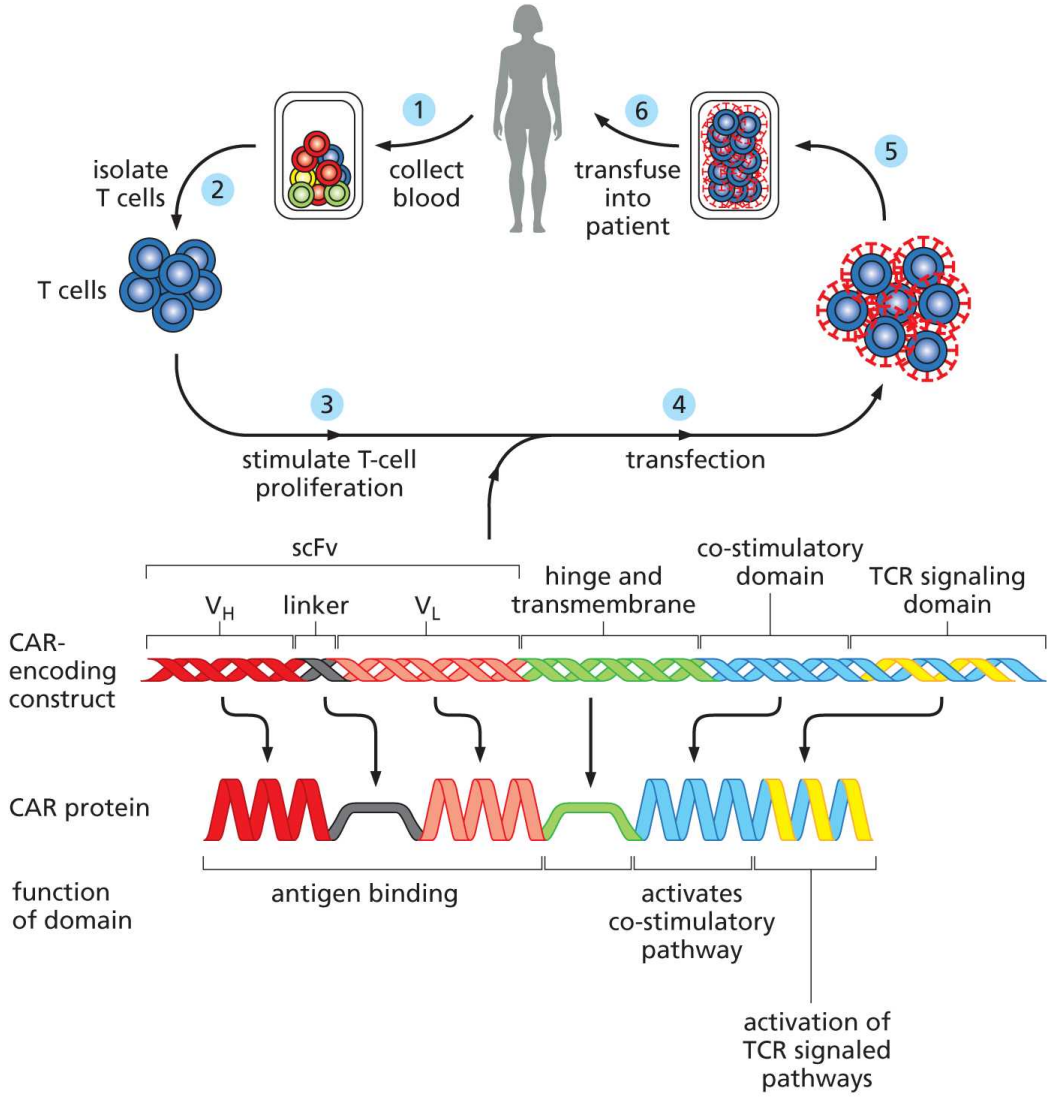
These multiple structural domains of a CAR allow it to incorporate all of the functional features required for its recognition of a target cell and the resulting functional activation of a T cell, all this achieved by a single engineered molecule (see Sidebar 16.7). Once a gene encoding a CAR has been assembled, it can be transfected into a patient's lymphocytes, resulting in the creation of CAR T cells.

An additional attraction of CAR T cells is that the antigen specificity of their CAR can be predetermined to be specific for recognizing and binding a tumor antigen known to be displayed on the surface of targeted cancer cells (see Figure 16.9B). Also, such a protein antigen can be displayed directly on the surface of the cancer cell's plasma membrane without a need for prior antigen processing and association with MHC-I molecules. (Of course, any resulting attack launched by a CAR-expressing T cell will fail if and when the cancer cell contrives to shut down expression of the targeted cell surface antigen.)

Like the antibodies from which they derive, antigen-specific CARs can be generated that recognize a variety of chemical classes of antigens, including not only proteins but also carbohydrates and lipids. In addition, the desired CAR T-cell responses involve the participation of only two cell types: the attacking CAR T cell and the targeted antigen-displaying cancer cell. This obviates the need for several different receptor–ligand interactions involving multiple cell types that are normally required for T-cell activation (see Figure 16.9).

Once the chimeric antigen receptor has been generated, the manufacture and administration of CAR T cells is carried out along the general outline illustrated in **Figure 16.10**. Thus, leukocytes are collected via leukapheresis of a patient's blood, a procedure in which white blood cells including T cells are separated from blood and the remaining red blood cells and plasma are recycled back to the patient. As illustrated in this figure, T cells are then separated from other leukocytes, transfected with an expression construct encoding the CAR, and stimulated to proliferate by antibody-mediated crosslinking using anti-TCR and anti-CD28 antibodies in the presence of IL-2. Following *ex vivo* expansion, the CAR-displaying T cells are infused back into a patient who, as in the adoptive T-cell transfer therapy described earlier, has been treated with leukocyte-depleting chemotherapy in order to create a niche in the patient's immune system for the re-introduced cells.

Patients also are given IL-2 to support longer-term CAR T-cell growth and maintenance. As attractive as CAR T-cell therapy is in concept, it remains encumbered by several significant complications (**Sidebar 16.8**).



A depiction of the Overall strategy of C A R T-cell therapy. Step 1 is to collect blood from a patient. Step 2 is to isolate T-cells. Step 3 is stimulate T-cell proliferation. Step 4 is transfection with a C A R encoding construct. The structure of the construct is shown, schematically, to consist, from left to right, of a V H domain, a linker, a V L domain, a transmembrane domain hinge, a co-stimulatory domain, and a T C R signaling domain. In the corresponding C A R protein, the segments produced by the V H and V L domains engage in antigen binding, the segment produced by the co-stimulatory domain activates the co-stimulatory pathway, and the signaling domain activates the T C R signaled pathways. Step 5 is the harvesting of the population of C A R-expressing T cells. Step 6 is transfusion into the patient.

Figure 16.10 Overall strategy of CAR T-cell therapy Production of CAR T cells must be tailored to each individual's tumors and associated tumor antigens. (1) Blood is collected from the patient and leukocytes are prepared by the procedure sometimes termed leukapheresis. (2) T cells are purified from the leukocyte fraction. (3) T cells are stimulated to proliferate by exposure to IL-2 and T-cell activation signals. (4) The proliferating T cells are transfected with a lentiviral or retroviral expression vector construct that encodes the chimeric antigen receptor (CAR, *lower left*). (5) The population of CAR-expressing T cells is harvested. (6) These cells are transfused into the patient who has undergone lymphodepletion prior to the return of these genetically modified T-cells. (Adapted from R.J. Lee, J.S. Abramson and R.A. Goldsby, *Case Studies in Cancer*, New York: W.W. Norton, 2019, pp. 296–297.)

Sidebar 16.8 The utility of ACT therapies is reduced by certain limitations

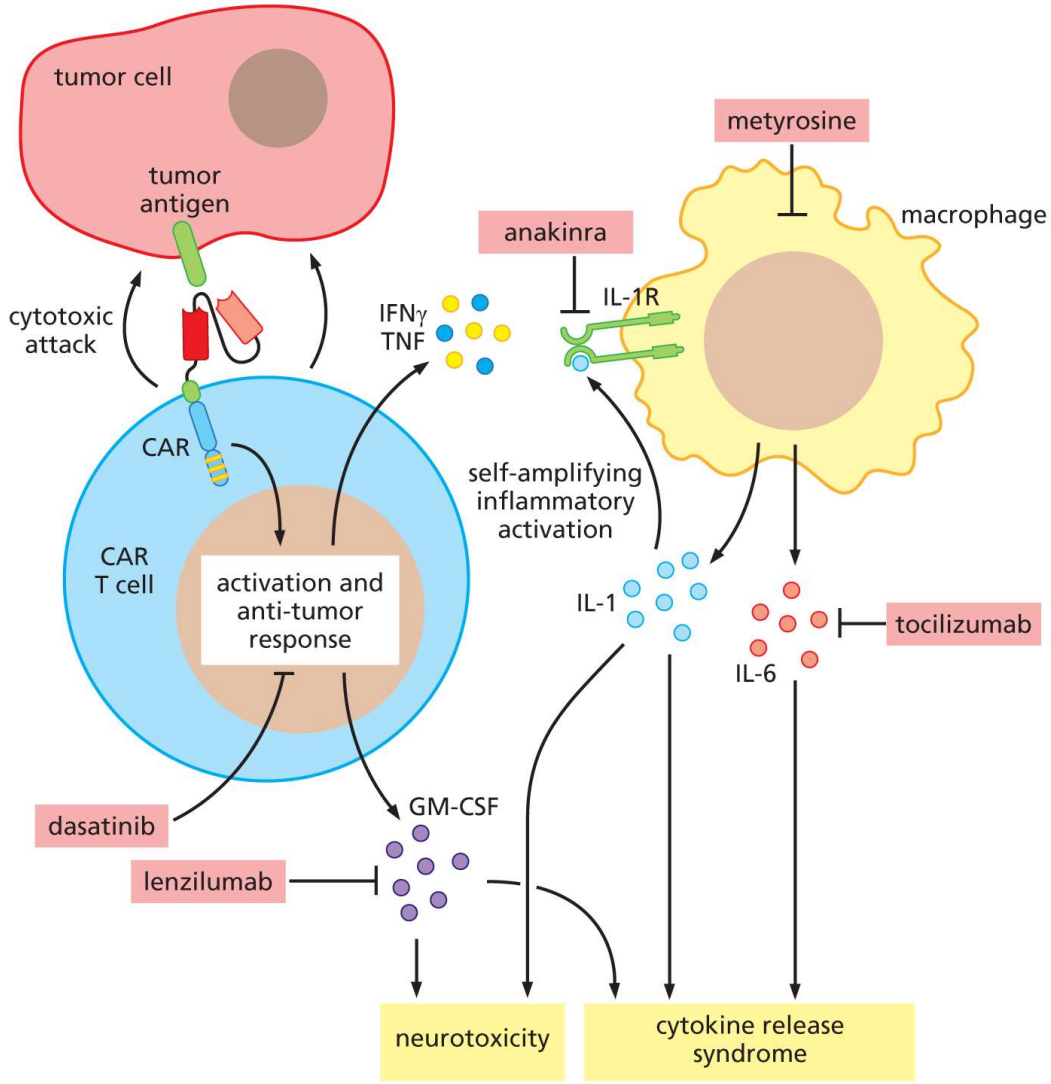
At present, like the adoptive cell transfer (ACT) therapies described earlier, CAR therapies represent personalized therapies designed to respond to each patient's tumor and associated antigens. Moreover, each batch of T cells that is modified to become CAR T cells must be autologous to the patient, that is, derived from a patient's own preexisting T cells. This requirement is critical in order to avoid a graft-versus-host (GVH) reaction, which often occurs when transfused donor T cells are derived from an allogeneic donor. Such allogeneic T cells may recognize and react to recipient host antigens displayed widely throughout a patient's body, resulting in a serious and potentially fatal condition.

In the case of CAR T-cell therapy, GVH may occur simply because, in addition to expression of the inserted CAR proteins, the modified T cells continue to express their normal complement of native TCRs. If allogeneic T cells are indeed employed to create CAR T cells (because a patient's lymphocytes are not readily available), these lymphocytes will not be tolerant following infusion of the modified T cells of some of the antigens naturally expressed by the recipient patient's tissues, particularly the protein products of the major histocompatibility complex genes, notably MHC-I and MHC-II. Recognition of these or other host antigens can lead to widespread GVH attacks on the recipient's cells that must be controlled with a variety of immunosuppressive treatments.

Another potential complication is that the CAR expressed by the introduced lymphocytes is itself a novel molecular structure not expressed by the patient's normal cells and therefore represents, on its own, a potentially immunogenic antigen capable of eliciting an immune response from the immune system of this recipient. This response can be minimized, however, by the immunosuppressive preparative lymphodepletion protocol mentioned above.

A prominent example of the use of CAR T therapy comes from its application to the treatment of B-cell-related lymphomas. Thus, the CD19 antigen is expressed by cells of the B-cell lineage at all stages of their differentiation (including derived lymphoma cells)

and therefore has represented an attractive candidate for antigen-targeted CAR T therapy. Indeed, anti-CD19–CAR T-cell therapy has become the current standard of care for patients suffering acute lymphoblastic leukemia (ALL) and large B-cell lymphoma. In spite of its demonstrated therapeutic efficacy, this treatment is often accompanied by significant side effects that on their own can be severe and even life threatening. Thus, within the first several weeks of therapy, patients often experience fevers as high as 40°C, with spikes in the production of a variety of inflammatory cytokines, particularly interferon-γ, IL-6, TNFα, GM-CSF, and IL-1. Together, these systemically released cytokines represent the central features of the condition termed cytokine release syndrome (CRS), which is manifested as an acute systemic inflammatory syndrome that can lead to the dysfunction if not destruction of multiple tissues, organs, and even neurological disorders. The life-threatening consequences of CRS can usually be avoided or treated by use of a variety of immunosuppressive treatments (**Figure 16.11**).



A diagrammatic overview of Cytokine release syndrome and some pharmacological approaches to its treatment. Upon activation and initiation of an anti-tumor response, a C A R T-cell begins a cytotoxic attack on a tumor cell whose antigen has been recognized. Associated with this activity is the release of interferon gamma, tumor necrosis factor, and G M-C S F. Activation of the T-cell and initiation of the anti-tumor response can be blocked by dasatinib. G M-C S F has neurotoxic effects and contributes to cytokine release syndrome, but lenzilumab can block G M-C S F from doing this. The release the of cytokines stimulates a macrophage to release interleukins 1 and 6. These also contribute to cytokine release syndrome, and I L 1 is neurotoxic. Metyrosine inhibits release of interleukins 1 and 6, and tocilizumab blocks the action of I L 6. Interleukin 1 engages in self-amplifying inflammatory activation by binding to I L 1 receptors on the macrophage, but this action is blocked by anakinra.

Figure 16.11 Cytokine release syndrome (CRS) and some pharmacological approaches to its treatment Activation of a CAR T cell (*light blue, lower left*; see also Figures 16.9 and 16.10) triggered by its encounter with a targeted tumor cell (*pink, upper left*) causes the CAR T cell to synthesize and secrete a number of powerful cytokines, including tumor necrosis factor (TNF, *dark blue*), interferon-γ (IFNγ, *yellow*), and granulocyte-macrophage colony-stimulating factor (GM-CSF) (*purple*). Macrophages (*light yellow, right*) respond to the highly pro-inflammatory cytokines in a number of ways, including secretion of IL-1 (*light blue*) and IL-6 (*pink*). In addition to its neurotoxic effects, IL-1 (*light blue*) interacts in an autocrine fashion with IL-1 receptors displayed by the macrophages (*light green*) to drive them to higher levels of activation, contributing to a positive feedback loop that intensifies CRS and its impact on the central nervous system (CNS). Anti-CRS therapies include treatment with anakinra, an IL-1 mimic that blocks the IL-1 receptor; lenzilumab, a monoclonal antibody that binds GM-CSF; and tocilizumab, a monoclonal antibody that binds IL-6. In addition, small-molecule therapies deploying desatinib and metyrosine have been used. Dasatinib, an inhibitor of the Src family of tyrosine kinases as well as Bcr-Abl, lowers the level of activation and cytokine secretion in CAR T cells. Metyrosine acts on macrophages to reduce their production of catecholamines, which function in turn as inducers of IL-6 secretion. (Adapted from R.C. Larson and M.V. Maus, *Nat. Rev. Cancer* 21:145–161, 2021. With permission from Nature.)

To date, CAR T therapies targeting the tumor-associated antigen described above and several others listed in **Table 16.4** have made their greatest contribution to the treatment of hematologic cancers. Efforts to deploy CAR T against solid tumors have been largely frustrated by the challenges of identifying target antigens that are strongly expressed within tumors but exhibit little or no expression in normal tissues. Still, several candidate antigens have emerged. These include the B7-H3 antigen, which is expressed at low levels

on the cells of many normal tissues, but at high levels by the cells of several pediatric cancers, including medulloblastoma, Ewing sarcoma, and osteosarcoma.

Table 16.4 Use of CAR T cells to treat a variety of hematologic cancers

Target antigen	Disease	CAR	Number of patients analyzed	Median age (years)	Response	Patients with CRS (%)	Patients with neurotoxicity (%)
CD19	B-ALL (pediatric)[a]	Tisagenlecleucel; 4-1BB co-stimulation	75	11	6-month relapse-free survival rate of 80%	77	40
CD19	relapsed or refractory DLBCL[a]	Axicabtagene ciloleucel; CD28 co-stimulation	101	58	83% objective response; 58% complete response	93	67
CD19	refractory B-cell lymphomas[a]	Tisagenlecleucel; 4-1BB co-stimulation	28	58.5	64% overall response; 43% complete remission	57	39
CD19	mantle-cell lymphoma[a]	Axicabtagene ciloleucel; CD28 co-stimulation	68	65	93% objective response rate; 67% complete response	91	63

Target antigen	Disease	CAR	Number of patients analyzed	Median age (years)	Response	Patients with CRS (%)	Patients with neurotoxicity (%)
CD19	B-ALL	CD28 co-stimulation	53	44	83% complete remission; median overall survival 12.9 months	85	44
CD22	relapsed or refractory pre-B-ALL	4-1BB co-stimulation	21	19	73% complete remission treated with higher dose	76	unreported
BCMA	relapsed or refractory multiple myeloma	Idecaptagene vicleucel; 4-1BB co-stimulation	33	60	85% objective response rate; 45% complete response rate	76	42
BCMA	multiple myeloma	4-1BB co-stimulation	25		48% overall response rate	88	32

B-ALL, B-cell acute lymphoblastic leukemia; BCMA, B-cell maturation antigen; CAR, chimeric antigen receptor; CRS, cytokine release syndrome; DLBCL, diffuse large B-cell lymphoma; 4-1BB TNF-related ligand protein.

Brain cancers have represented a challenge for mAb-based cancer therapies because of the difficulties imposed by the blood–brain barrier, specifically its ability to block the transfer of large molecules from the circulation into the brain parenchyma. Conveniently, however, a quirk in brain physiology allows intravenously injected T cells to pass through the blood–brain barrier and gain access to the brain parenchyma. This fact has provoked considerable interest in developing CAR therapies for the treatment of glioblastomas.

OceanofPDF.com

Glossary

chimeric antigen receptor
: Cell surface antigen-binding receptor generated by recombinant DNA in which antigen-binding and transmembrane domains have been fused with segments of intracellular signal-emitting domains, resulting in strong potentiation of antigen-provoked signaling within a T cell.

single-chain variable region fragment
: An antigen-binding polypeptide that is formed by connecting the variable domains of the heavy and light chains of an immunoglobulin via an intermediate linker; this fusion protein can function like the parental, naturally formed antibody to recognize and bind a specific antigen.

leukapheresis
: Procedure whereby leukocytes are prepared *ex vivo* from drawn blood prior to returning the remaining portions of the blood to the donor or to another recipient.

cytokine release syndrome
: Condition representing acute systemic inflammation associated with fever and often the dysfunction of multiple organs throughout the body, which is often life-threatening.

graft-versus-host disease
: A condition, often life-threatening, in which cells of an allogeneic bone marrow graft generate significant immune-mediated destruction of various normal tissues throughout the body of the graft recipient.

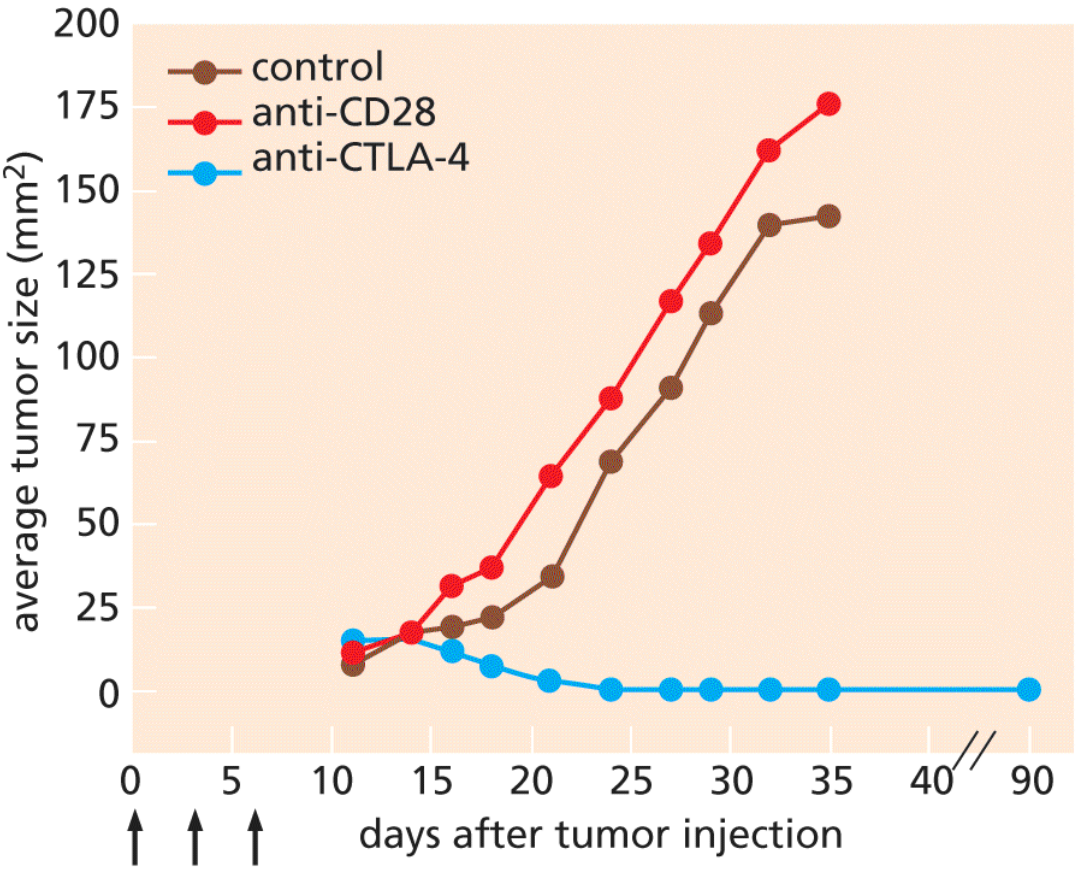
16.9 Checkpoint inhibition is a distinct type of immunotherapy that modifies the behavior of immune cells

The antibody and T-cell-mediated immunotherapies we have examined so far are designed to directly engage and kill tumor cells. Checkpoint inhibitory therapies operate quite differently. Rather than launching direct cytopathic attacks on these cells, this class of treatments manipulates the immune system in ways that increase the likelihood and potency of *existing* anti-tumor immune responses, particularly responses that may already exist in a patient's body but cannot be launched or effectively sustained because they have been shut down by certain immune regulatory mechanisms.

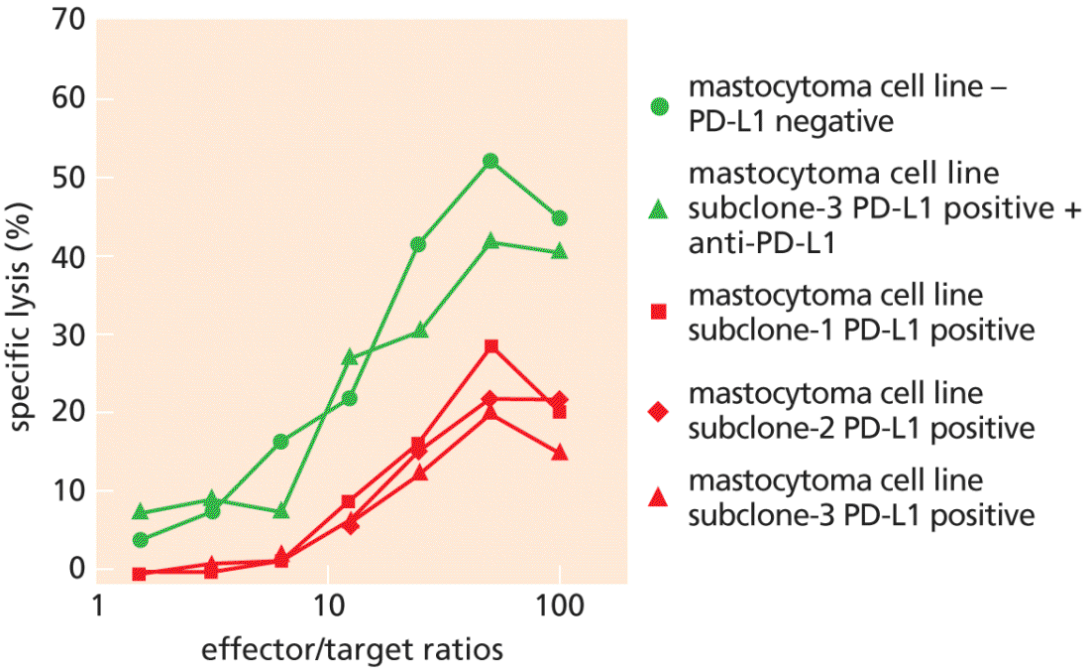
Checkpoint inhibition was introduced in Chapter 15 as a mechanism that operates to restrain excessive T-cell activation that might otherwise lead to persistent inflammatory states or autoimmune diseases. In effect, immune checkpoints of various types operate to provide negative-feedback controls on normal immune function (see also Section 6.14), thereby ensuring that the occurrence and strength of various immune responses are constrained in order to avoid inadvertent, uncontrolled, highly destructive autoimmune attacks on normal cells and tissues.

The concept of immune checkpoint regulation and associated anti-tumor immunotherapy emerged from a foundational experiment reported in 1996. As illustrated in **Figure 16.12A**, this work demonstrated the principle of checkpoint immunotherapy by showing that antibody-mediated blockade of CTLA-4 function inhibits tumor growth. This result was most provocative, because it showed that an antibody directed against a T-cell protein (rather than a cancer cell-associated antigen) would impede the growth of a tumor.



A line graph depicting average tumor size over time for three different groups. In the control group, tumors grew to 125 square millimeters in surface area within 30 days of tumor injection. Tumors grew even more in the anti-C D 28 group, to 150 square millimeters within 30 days. In the anti-C T L A-4 group, by contrast, tumors shrank to zero within 30 days and remained at zero out to 90 days.

(A)



A line graph charting specific lysis percentage as a function of effector to target ratio for five different mastocytoma cell lines. The horizontal scale is logarithmic. The curves rise from 1 to 10 and from 10 to 50 but then fall after 50, so that peak lysis percentages are at an effector-to-target ratio of 50. The P D-L1 negative line has the highest lysis percentages, peaking at a specific lysis of about 53. Next is subclone-3 P D-L1 positive and anti-P D-L1, peaking at about 43 percent. Subclone-1 P D-L1 positive peaks at just under 30 percent, and subclone-2 P D-L1 positive and subclone-3 P D-L1 positive both peak at about 20 percent.

(B)

Figure 16.12 Enhancement of anti-tumor immunity by antibody-mediated checkpoint blockade (A) Effect of CTLA-4 blockade. Cells of a colon cancer cell line were implanted into three groups of mice on day zero. The treated groups received either anti-CTLA-4 moAb (*blue*) or anti-CD28 moAb (*red*) at the three times indicated by the arrows, while the control group (*brown*) received neither. Tumor growth was assessed by measuring the size of the tumor nodule. (B) Effect of PD-1 blocking PD-L1 interaction. The targeted cancer cells used were from a cell line that had been derived from a mouse mastocytoma, which arises from mast cells and represent a subtype of granulocytes of the myeloid lineage. These cells did not naturally express PD-L1. Three subclones of the line were transfected with a PD-L1 expression construct to force their expression of PD-L1. Each of these populations was subjected to attack by a cytotoxic T-cell line *in vitro* at increasing ratios of the attacking cytotoxic T-cell line (effectors) to the

mastocytoma target cell line (target) and the lysis of targeted mastocytoma cells was measured. The three PD-L1-expressing mastocytoma subclones showed reduced sensitivity to killing (*red lines*) relative to parental mastocytoma cells that were PD-L1 negative (*green filled circles*). Moreover, when the subclone-3 cells, which had been forced to express PD-L1 were treated with anti-PD-L1 moAb (*green filled triangles*), their sensitivity to killing rivaled that of the parental cell line (*green filled circles*) that lacked forced PD-L1 expression. (A, adapted from D.R. Leach, M.F. Krummel and J.P. Allison. *Science* 271:1734–1736, 1996. With permission from AAAS. B, adapted from Y. Iwai, M. Ishida, Y. Tanaka et al. *Proc. Natl. Acad. Sci. USA* 99:12293–12297, 2002. With permission from National Academy of Sciences, U.S.A.)

While we have discussed the importance of checkpoint controls in limiting the direct attacks by CTLs on potential target cells, these controls also operate to constrain an earlier step in the development of CTLs that operates *centrally* in the lymph nodes rather than *peripherally* at sites of immune attack on tumors. Recall that CTLA-4 acts as a cell surface receptor displayed by T lymphocytes that is activated by binding its cognate ligands displayed by antigen-presenting cells in the lymph nodes (see Sections 15.7 and 15.12). Since its ligands (usually termed CD80 and CD86) are cell surface proteins displayed by other cells, specifically APCs, they have sometimes been termed "counter-receptors." Upon engagement with CD80/86, which requires close physical contact between T cells and APCs displaying their cognate antigens, the CTLA-4 receptor normally acts directly to shut down T-cell receptor signaling and thus T-cell activation in both CD4+ and CD8+ T cells. Hence, introduction of an anti-CTLA-4 mAb severs an important negative-feedback loop that normally operates within lymphoid tissues to constrain T-cell activation. Accordingly, this moAb treatment enables the activation of both CD8+ T cells that are capable of becoming cytotoxic T lymphocytes (CTLs, T_C) and CD4+ helper T-cell (T_H) subsets that make important contributions to anti-tumor immunity.

While the 1996 work did not reveal these mechanistic details, it did show unequivocally that manipulations of immune cells, in this case CTLs, led to major changes in the ability of tumors to persist and continue to grow in host mice. This suggested, in turn, that the immune systems of the tumor-bearing hosts intrinsically possessed the power to kill cancer cells. However, this hypothesized power could not be realized in the absence of experimental intervention, in this case an intervention achieved through the use of an antibody recognizing a cell surface protein (CTLA-4) displayed by T cells.

In fact, the 1996 work could have been interpreted in two ways: either the applied antibody directly *stimulated* the anti-tumor response of the mice treated with it or,

alternatively, it *interrupted* a normally operative inhibitory mechanism that blocked their ability to mount an effective anti-tumor response. As is clear from the last chapter and the above text, it was this second mechanism that was found to underlie and explain the mechanism of action of the anti-CTLA-4 moAb.

The observed successes in halting tumor growth suggested a larger principle: checkpoint controls analogous to the CTLA-4:CD80/86 regulation highlighted in these early experiments operate to protect cancer cells from attack and elimination, and conversely, blocking these negative controls can free certain arms of the immune system from suppression by these controls. This liberation from such postulated controls would then give T cells the freedom to launch effective attacks on cancer cells, ideally resulting in elimination of the latter.

Control experiments, undertaken in parallel, involved the CD28 co-receptor, which is also displayed on the surface of T cells. This second set of experiments demonstrated that CD28 acts in a manner that is precisely opposite to CTLA-4, doing so by *enabling* the generation of CTL-mediated immune attack. Thus, if the CD28 stimulatory receptor co-displayed with the TCR on the surface of a T lymphocyte was able to engage CD80/CD86 displayed by APCs, it would provide the co-stimulation necessary to enable the activation of CD8 T cells and their maturation into CTLs capable of mounting cytolytic attacks, notably attacks on targeted tumor cells. (As might be anticipated, blocking this CD28 receptor with an appropriate mAb led to a result opposite to that achieved by anti-CTLA-4 mAbs, namely that tumor growth actually *benefited* by squelching the actions of this activation-promoting CD28 protein.

These functions of CTLA-4 represent a two-edged sword. Normally, CTLA-4 provides critical protection against excessive or inappropriate initiation of immune responses launched by T cells, such as those that can lead to autoimmune diseases. However, at the same time, it can reduce or even prevent the initiation of desirable T-cell responses including those mounted against cancer cells.

In addition, subsequent work has shown that anti-CTLA-4 moAb has another mechanism of action: It contributes to the killing of regulatory T cells (T_{reg}) cells that, when allowed to function, are potently immunosuppressive cells that inhibit both CD4+ and CD8+ T cells. (Regulatory T cells display CTLA-4 on their surface, making them targets for the binding of anti-CTLA-4 antibodies, which leads to their death mediated by either natural killer (NK) cells or phagocytes as described in Section 16.4 and illustrated in Figure 16.4.)

An entirely independent set of studies uncovered PD-1, a second, distinct inhibitory checkpoint receptor displayed by CTLs and other T cells that operates at a later stage of T-cell development, after activated T cells have ceased their interactions with APCs, left lymphoid tissues, and dispersed into tissues throughout the body (**Sidebar 16.9**).

Sidebar 16.9 CTLA-4 and PD-1 act at distinct steps of CTL activation

As described here, the two checkpoint controls actually operate at distinct, successive stages of CTL development. Initial activation of naive T cells occurs within lymph nodes, where antigen-presenting cells (APCs) present antigen to developing T cells (see Sections 15.7 and 15.12). This initial confrontation arms the T cells, allowing them to develop into functional CTLs and to disperse to peripheral, non-lymphoid tissues throughout the body. CTLA-4 damps down this initial priming in lymph nodes and other lymphoid tissues, explaining why anti-CTLA-4 can potentiate the priming of T cells that normally occurs within lymphoid tissues.

PD-1 appears on the surface of T cells that have already been primed in lymphoid tissues, as described above, but operates instead at a later phase of T-cell development, doing so in the context of non-lymphoid peripheral tissues. This explains how PD-1 actions interfere directly with the interactions between CTLs and their potential targeted cells in various anatomical sites throughout the body; these PD-1 functions therefore operate only *after* primed CTLs have emigrated from lymphoid organs and dispersed throughout the body.

As mentioned, engagement of PD-1 with its cognate ligands PD-L1 and PD-L2 displayed by target cells only occurs if and when CTLs encounter antigen-expressing target cells. Once this encounter has taken place, the PD-1:PD-L1/2 interaction proceeds to inhibit both T-cell cytotoxicity and the secretion of inflammatory cytokines, such as IFNγ and TNFα, by antigen-activated CTLs. In addition to its inhibition of T-cell cytotoxicity, we now know that the display of PD-1 ligands by potential target cells can be up-regulated by inflammatory cytokines, such as IFNγ and TNFα, that are secreted by CTLs, pointing to the PD-1:PD-L1/2 axis as a negative regulator of inflammation in peripheral, non-lymphoid tissues.

Importantly, because these two checkpoint controls (involving CTLA-4 and PD-1) operate at successive stages of T-cell activation, inhibiting both of them with mAbs directed against the two signaling axes can have additive or even synergistic effects in terms of activating ongoing immune attack. However, while the use of mixtures of moAbs interrupting both checkpoints may have increased potency in eliminating tumors, it can often elicit unacceptably high levels of autoimmune conditions in patients under treatment.

The discovery of the PD-1 receptor was followed by research that revealed and characterized PD-L1 and PD-L2, two ligands of the PD-1 receptor displayed on the surface of potential target cells. These ligands are routinely expressed on the surfaces of a variety of cell types throughout the body that might fall victim to CTL cell attack.

Figure 16.12 describes an experiment conducted *in vitro* and employing a PD-1-expressing cytotoxic T-cell line whose TCRs were specific for an antigen expressed by the target P815 tumor cells employed in this particular experiment.

In more detail, the PD-1-expressing CTLs killed their P815 targets perfectly well if the cognate PD-L1 was missing from the surface of the targeted P815 tumor cells. However, forcing PD-L1 expression in the P815 tumor cells, achieved experimentally with an introduced expression vector, rendered these cells less susceptible to killing by the cytotoxic T cells. Hence, the previously observed killing of the target cells proceeded efficiently as long as these P815 target cells failed to express the PD-L1 ligand, but was greatly reduced once these P815 cells were forced to express PD-L1.

Importantly, as shown in Figure 16.12B, in the presence of anti-PD-1 antibody, even PD-L1-displaying cells fall victim to attack by PD-1-expressing CTLs. These experiments demonstrated that blockade of the PD-1/PD-L1 checkpoint by anti-PD-1 relieved inhibition of CTL-mediated immune responses. The PD-1/PD-L1 work established the principle that there are checkpoint regulatory mechanisms beyond the CTLA-4:CD80/86 signaling axis. Indeed, subsequent work has found yet other receptor:ligand pairs that operate to inhibit T-cell responses (**Table 16.5**). As might have been anticipated, these initial *in vitro* experiments could be extended to demonstrations *in vivo*, which confirmed that attacks on tumors formed by targeted cells could be predicted on the basis of their *in vitro* responses to certain CTLs. To summarize, use of anti-CTLA-4 or anti-PD1 moAbs demonstrated that the survival of mouse hosts bearing various tumors could be extended by antibody-mediated blockade of these two checkpoint controls (see Sidebar 16.9).

Table 16.5 Immune checkpoint inhibitors in clinical use and under development

Immune checkpoint		**Immune checkpoint inhibitor (ICI)**	**FDA approval**	**Treatment indications**
ICIs in clinical use				
Receptor	**Ligand**			
CTLA-4	CD80/86	anti-CTLA-4 (ipilimumab)	first in 2011,	metastatic melanoma and others

Immune checkpoint		Immune checkpoint inhibitor (ICI)	FDA approval	Treatment indications
ICIs in clinical use				
Receptor	**Ligand**			
			other ICIs since	
PD-1	PD-L1, PD-L2	anti-PD-1 (pembrolizumab, nivolumab, others)anti-PD-L1 (durvalumab, atezolizumab)	first in 2014, other ICIs since first in 2016, other ICIs since	metastatic melanoma and subsequently many othersmetastatic urothelial carcinoma and others
ICIs in advanced clinical trials				
1**Receptor**	**Ligand**	**Nature of IC**	**Immune process impacted by the immune checkpoint**	
LAG-3	MHC-II	moAb[a]	inhibition of T-cell proliferation and cytokine secretion; may promote expansion of T_{reg}'s	
TIM-3	Galectin-9, CEACAM-1	moAb	induces T-cell exhaustion and can affect other immunocytes including NK cells and some dendritic cells	

Immune checkpoint		Immune checkpoint inhibitor (ICI)	FDA approval		Treatment indications
ICIs in clinical use					
Receptor	**Ligand**				
PVRIG	PVRL2	moAb	engagement of T-cell-borne PVRIG with PVRL2 on dendritic cells inhibits T-cell activation		
VISTA	PSGL-1, VISIG-3	moAb	inhibits T-cell activation and cytokine production; inhibits NK-cell responses; inhibits secretion of TNF and certain other proinflammatory cytokines by myeloid cell types		
TIGIT	CD155	moAb	inhibits T-cell and NK-cell effector functions; can increase T_{reg}-mediated immunosuppression		
CD47	SIRPα	moAb[a]	inhibition of phagocytosis by macrophages

16.10 Checkpoint immunotherapies based on mouse studies have been applied in the oncology clinic

We turn now to an examination of the translation of these studies of checkpoint immunology to actual clinical applications of these immunotherapies. As shown in Table 16.5, ipilimumab, an anti-CTLA-4 mAb, was the first checkpoint inhibitor to receive FDA approval for the treatment of cancer. It showed survival benefits and improvements in overall survival when used to treat melanoma patients. Soon thereafter, an anti-PD-1 antibody also showed substantial clinical benefit for the treatment of melanoma, and it too received FDA approval (see Table 16.5). In the years since the introduction into clinical practice of these first immune checkpoint blockade inhibitors (ICIs), many clinical trials against a wide variety of cancers have shown a highly variable efficacy of these immunotherapies for the treatment of many types of cancer, with few recapitulating the striking long-term therapeutic benefits of the anti-melanoma therapies (**Sidebar 16.10**).

Sidebar 16.10 Immune checkpoint blockade can yield unprecedented responses in human cancer patients

We can learn much from reviewing a critical clinical trial, aptly titled Checkmate 067, that compared the clinical performance of an anti-CTLA-4 ICI with an anti-PD-1 ICI and with a combination therapy employing both ICIs. Checkmate 067 enrolled into a clinical trial a patient population of 945 individuals who bore histologically confirmed stage III or stage IV metastatic melanomas and had received no prior systemic treatment such as chemotherapy or moAb therapy. Historical controls, that is, the documented clinical responses of patients to various earlier anti-melanoma therapies, indicated that patients under treatment for these conditions would have an overall survival rate of 23% at five years after initial diagnosis.

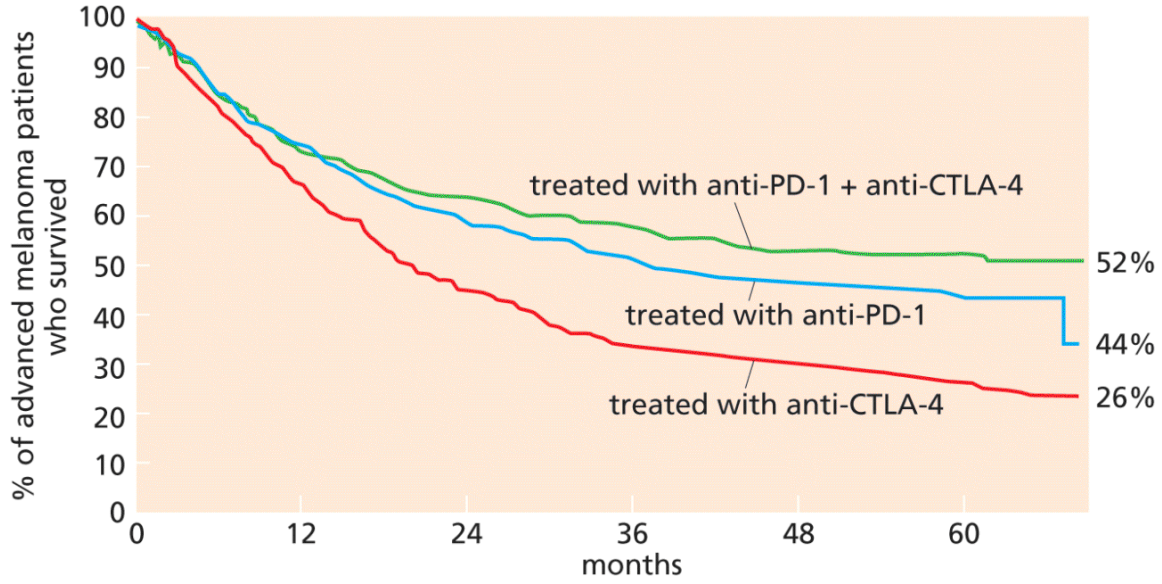
Each of the participants in this trial was assigned to one of the following groups: anti-PD1 alone, anti-CTLA-4 alone, or anti-CTLA-4 + anti PD-1. As anticipated from previous studies of anti-CTLA-4 and anti-PD-1 ICIs, some patients in each of the three treatment groups showed significant clinical responses. However, the data in **Table 16.6** indicate that responses differed significantly among each of the treatments. Thus, patients enrolled in the anti-CTLA-4 cohort showed inferior responses to therapy relative to those enrolled in the other two in all respects; at the same time, patients whose tumors were better controlled also experienced higher incidence of side effects.

Table 16.6 Responses of melanoma patients to ICI monotherapy or combination therapy

	Nivolumab plus ipilimumab (N = 314)		**Nivolumab (N = 316)**		**Ipilimumab (N = 315)**	
	N	**%**	**N**	**%**	**N**	**%**
Complete response[a]	69	22	60	19	18	6
Partial response[a]	114	36	81	26	42	13
Total responding	183	58	141	45	60	19
Patients experiencing high-grade adverse events[b]	186	59	73	23	69	28
5-year overall survival (patients alive 5 years after initiation of treatment)	151	52	130	44	67	26

	Nivolumab plus ipilimumab (N = 314)	Nivolumab (N = 316)	Ipilimumab (N = 315)
Median treatment-free interval in months[c]	18.1	1.8	1.9

The data in **Figure 16.13** illustrate the changes in tumor burden, a term referring to the size of the tumor or number of tumor cells carried by each patient in each of the treatment groups. These observations reveal a substantial contrast in the efficacy of the anti-PD-1 versus anti-CTLA-4 blockade therapies. We can also note that a significant percentage of the patients treated with only anti-PD-1checkpoint immunotherapy experienced durable progression-free survival (PFS) and overall survival (OS). A 5-year follow-up study of the patients enrolled in Checkmate 067 revealed leveling off ("plateauing") in survival beginning around 3 years after initiation of therapy that was maintained for another 5 years. In fact, the absence of additional patient deaths over this period, which yielded the horizontal plateaus in overall survival curves (see Figure 16.13), is often interpreted to represent definitive cures of neoplastic disease, which otherwise are rarely claimed in most types of currently available treatments of high-grade cancers of various types.



A line graph describing survival percentage of advanced melanoma patients as a function of time, for three different treatment groups. All three curves decline exponentially from 100 percent at time zero. At 60 months, the survival percentage was 26 for patients treated with anti-C T L A-4, 44 for patients treated with anti-P D-1, and 52 for patients treated with both.

Figure 16.13 Therapeutic efficacy of immune checkpoint inhibitors used singly or in combination The overall survival at 5 years was studied in three groups of melanoma patients treated with different versions of anti-checkpoint blockade moAbs. One group was treated with anti-CTLA-4 moAb (*red curve*), a second with anti-PD-1 moAb (*blue curve*), and a third group received both anti-PD1 and anti-CTLA-4 moAbs (*green curve*). The combination was superior to either anti-CTLA-4 or anti-PD-1 used alone. (Adapted from J. Larkin, V. Chiaron-Seleni, R. Gonzalez et al. *N. Engl. J. Med.* 381:1535–1546, 2019. With permission from Massachusetts Medical Society.)

The 5-year survival rates for patients presenting in the clinic with metastatic melanomas has, until recently, hovered in the range of 23%, as mentioned above. In contrast, the therapies involving anti-PD-1 alone, anti-CTLA-4 alone, and the combination of anti-CTLA-4 + anti-PD-1, were 44%, 26%, and 52%, respectively (see Figure 16.13). These survival rates of metastatic melanoma patients are unmatched by any non-ICI therapies. So far, only adoptive T-cell therapy, a highly customized and resource-intensive adoptive cell transfer immunotherapy (see Section 16.7), has produced comparable rates of success. At present, ICI therapy is used for many types of cancer and several ICIs have received FDA approval for such therapy (see Table 16.5).

Unfortunately, the impressive success delivered by ICIs in treatment of melanoma have not yet been seen in the treatment of most other types of cancer. Nevertheless, the list of cancers responsive to treatment with ICIs is increasing. More generally, because mutation can generate neoantigens, some of these being subject to targeting by the immune system, cancers that harbor elevated numbers of mutations are likely to provoke immune attack. Therapy of these cancers may benefit from the use of ICIs.

16.11 Resistance to immune checkpoint inhibitors commonly arises

Even among patients being treated for melanoma, a disease for which ICIs have had their greatest successes, the tumors borne by roughly half of these patients are either entirely unresponsive or the responses that are observed are only transient. Such responses are reminiscent of the responses of many types of tumors to a wide variety of anti-cancer therapies, as will be described in Chapter 17. As with chemotherapy, resistance to ICIs may be primary or acquired. Thus, in the cases of primary resistance, a significant, measurable response to immune checkpoint blockade (ICB) therapy is never observed, whereas patients with acquired resistance respond initially and only thereafter become refractory to treatment as therapy continues. Nonetheless, such acquired resistance after months of initial clinical responses may buy patients many months of symptom-free survival that they otherwise would not have enjoyed.

Cases of primary resistance may be ascribed to a variety of mechanisms. These may occur if there has not been any preexisting recognition of tumor cells by the adaptive immune system and therefore no low-level immune attacks that could be amplified by ICI therapy. This might derive from the failure of tumor cells, for whatever reason, to generate or present, via MHC-I proteins, peptide antigens to T cells, leading to the absence of a T-cell response of any kind. Similarly, there may be no T-cell response to enhance if the diverse array of T cells that succeed in entering into the interstices of a tumor lack subpopulations bearing TCRs that can recognize antigen-derived peptide:MHC complexes displayed by the tumor cells.

Even if all these obstacles to ICB inhibition were to be removed in the future, clinical responses to ICIs might still be compromised by changes *within* tumor cells, specifically interruptions of signaling pathways that are essential for effective killing by CTLs. As a prominent example, the

disruption in tumor cells of the signaling pathway activated by the interferon-γ (IFNγ) receptor comes to mind. Cancer cells lacking an intact IFNγ signaling pathway would be oblivious to the powerful anti-neoplastic effects of this T-cell-derived cytokine, which normally include a heightened susceptibility to apoptosis, an inhibition of proliferation, and an increased MHC class I-mediated antigen presentation (making them more vulnerable to immune recognition and attack). Such crippling of a cancer cell's capacity to respond to IFNγ denies patients the beneficial effects of increased IFN production, which ideally should occur once inhibitory checkpoints are eliminated by immune checkpoint inhibitors.

All of the mechanisms underlying primary resistance may also be developed by tumor cells during the course of ICI treatment, yielding multiple alternative paths to acquired resistance to immune checkpoint blockade. Finally, in addition to tumor cell-intrinsic pathways to ICI resistance, the tumor microenvironment (TME) can become a major tumor cell-extrinsic contributor to acquired ICI resistance. Populations of immunosuppressive cell types, including regulatory T cells (T_{reg}'s), M2-like macrophages, and myeloid-derived suppressor cells (MDSCs), create immunosuppressive TMEs that develop high levels of immunosuppressive cytokines such as TGFβ. This dictates that the evolution of an increasingly immunosuppressive TME during the course of checkpoint immunotherapy will deny a patient the therapeutic benefit that a T-cell-mediated anti-tumor response might otherwise provide. In recent years a variety of markers have been developed that help to predict responses to checkpoint immunotherapy (**Supplementary Sidebar 16.2**).

OceanofPDF.com

Glossary

primary resistance
: Term denoting the behavior of a tumor that is refractory to treatment from the onset of that treatment; *also termed* **intrinsic resistance**. *See also* **secondary resistance**.

acquired resistance
: Referring to the resistance to therapy of a tumor that arises with some delay following and in response to implementation of therapy; *also termed* **secondary resistance**. *See also* **intrinsic resistance**.

immune checkpoint
: Control mechanism ensuring that immune attacks on cells and tissues are constrained or limited, achieved by modulating downstream signaling responses such as those triggered by receptor–ligand interactions between immunocytes and target cells. *See also* **checkpoint**.

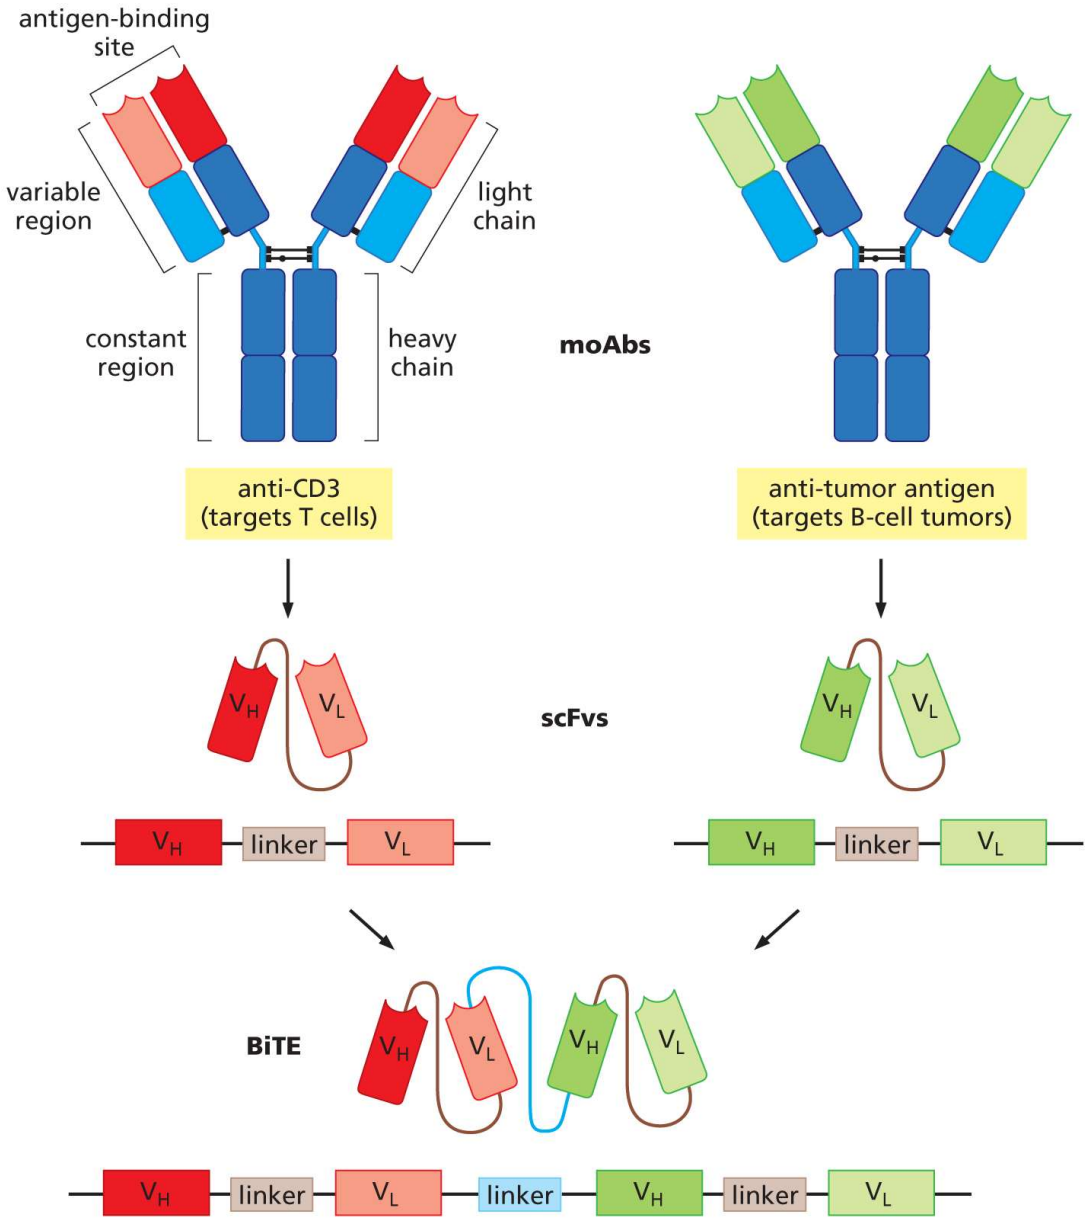
16.12 Lethal encounters between T cells and cancer cells can be encouraged by constructing bi-specific antibodies

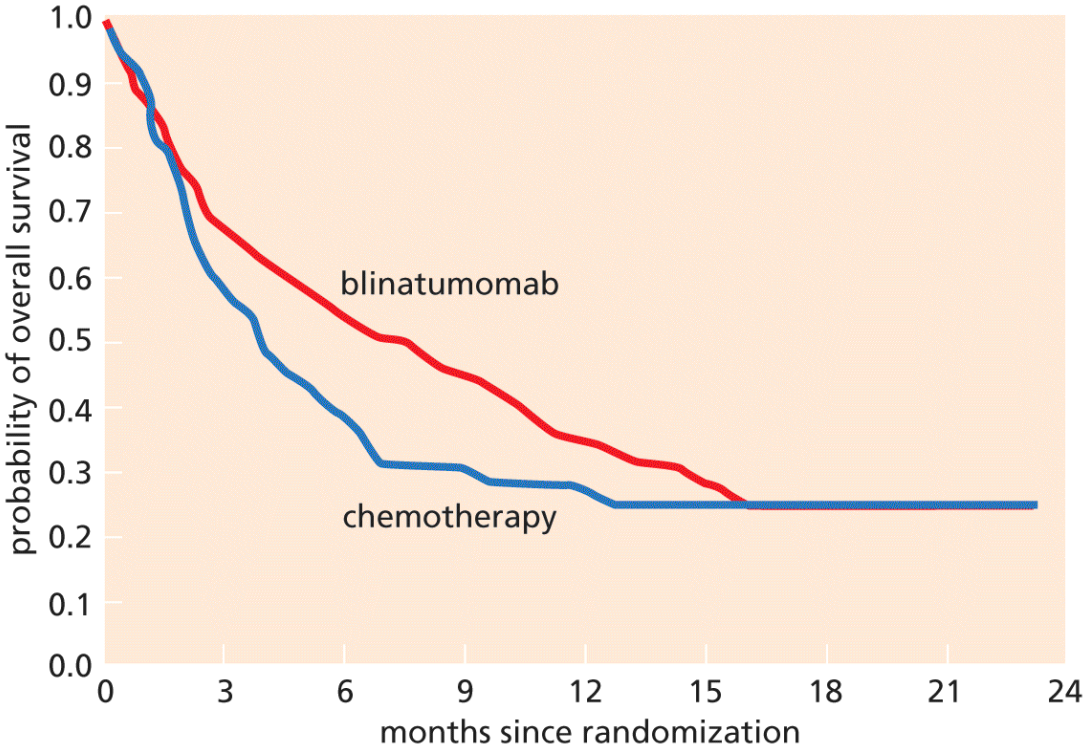
As discussed earlier in the context of CAR T-cell construction (see Sidebar 16.7), recombinant DNA procedures can be employed to join the reading frames encoding the variable domains of the heavy (H) and light (L) chains of a single antibody, the two being linked via a segment encoding a flexible linker to enable the formation of a functional antigen-combining site. If constructed properly, the fusion protein encoded by these joined engineered DNA segments should have antigen-binding power equivalent to that of the corresponding naturally arising antibody molecule.

This sequence of steps can be repeated with the DNA segments encoding a second, independently arising antibody having a different antigen-binding specificity (**Figure 16.14**). Thereafter, DNA segments encoding the H–L fusion proteins derived from the two distinct antigen-specific antibodies can be fused together, resulting in a DNA construct that now encompasses four reading frames and encodes two sets of H–L fusion proteins. The resulting bi-specific protein should now be able to simultaneously recognize and bind two distinct antigens and, by doing so, cross-link, for example, two cells, each expressing one of the two antigens recognized by this bi-specific protein.



Construction of a bi-specific anti-C D 3 x C D19 antibody begins with two monoclonal antibodies, one of which is an anti-C D 3 that targets T cells, and the other of which is an anti-tumor antigen that targets B-cell tumors. Each donates one heavy-chain binding-site end and one light-chain binding-site end, joined end-to-end by a linker to form a single-chain variable region fragment. The two fragments are then joined end-to-end by a third linker to form a linear bi-specific T-cell engager.

(A)



A line graph showing probability of overall survival as a function of time, for two different treatment groups. 7 months after randomization, 50 percent of patients treated with blinatumomab survive, compared to just over 30 percent of patients treated with standard chemotherapy. 17 months after randomization, however, the survival rate is the same for both groups, at 25 percent.

(B)

Figure 16.14 Construction and clinical trial of a bi-specific anti-CD3xCD19 antibody (A) The DNA sequences encoding the variable regions (V_H and V_L, *red, pink)* of a monoclonal antibody specific for CD3 (*above left*), a component of the T-cell receptor displayed by all T cells, and the sequences encoding the V_H and V_L sequences (*light green, dark green*) of a monoclonal antibody specific for CD19 (*above right*), a cell surface antigen displayed by B cells, were determined and used to design expression constructs encoding, in each case, single-chain variable region fragments (scFvs) that replicated the antigen specificity of each of the parent antibodies (*middle, left and right*). The DNA sequences encoding these two scFvs were linked to one another via a DNA segment encoding a connecting linker (*light blue*) which then expresses a protein termed a bi-specific T-cell engager (BiTE, *below*) that can bind to a B cell via its anti-CD19 specificity and to a T cell using its anti-CD3 arm. Such molecules can force the physical engagement of a T

cell with a CD19-bearing cell. (B) Clinical trial of a BiTE. The efficacy of blinatumomab, an anti-CD3xCD19 BiTE was compared to standard chemotherapy for the treatment of advanced acute lymphoblastic leukemia. As shown in the graph, the bi-specific antibody was superior to chemotherapy by increasing short-term survival but not overall long-term survival. (A, adapted from Slaney et al., *Cancer Discov.* 8:924–934, 2018. With permission from American Association for Cancer Research.B, adapted from H. Kantarjian, A. Stein, N. Gökbuget et al., *N. Engl. J. Med.* 376:836–847, 2017. With permission from Massachusetts Medical Society.)

Such cross-linking can be highly useful in the case of cancer immunotherapy because it may be used to physically link a CTL (or other cytotoxic cell) to a targeted cancer cell, thereby circumventing the complex biological steps that are normally required to place the two cells in close juxtaposition. Constructs like these can be loosely termed "bi-specific antibodies," even though they contain only the antigen-binding domains of two parental antibodies.

In one well-studied application of this procedure, a DNA construct encoding a bi-specific antibody was created by joining the reading frames encoding the binding sites of an anti-CD19 antibody with the binding sites of an anti-CD3 antibody. The resulting dual->specificity antibody was denoted anti-CD3xCD19. As mentioned earlier in this chapter (see Section 16.8), many tumors of the B-cell lineage, including B-cell lymphomas, display the CD19 B-cell-specific cell surface antigen; at the same time, virtually all T cells display CD3, which is a component of the multi-subunit TCR complex. Accordingly, a bi-specific anti-CD3xCD19 antibody should be able to simultaneously bind a T cell to a potential target cell of the B-cell lineage (see Figure 16.14A). Such an antibody that is specialized to link a T cell to potential cell targets is sometimes termed a bi-specific T-cell engager (BiTE). The T cell in this forced marriage can be a CTL, and this association, once formed, can be used, in the case of B-cell lymphomas, to drive a functional engagement of T cells with lymphoma cells. Some of the cross-linked T cells may even carry a TCR (which continues to be expressed in these modified cells) that recognizes an antigen displayed by the targeted B cells, resulting in an immune-mediated cytotoxic attack and elimination of the B cells and the tumors that they form.

Clinical trials have demonstrated the effectiveness of BiTEs for the treatment of certain cancers, including one landmark study that compared the effectiveness of blinatumomab—an anti-CD3xCD19 BiTE consisting of an anti-CD19 single-chain variable fragment (scFv) joined to an anti-CD3 scFv—applied together with chemotherapy for the treatment of advanced acute lymphoblastic leukemia (ALL). Historically, although chemotherapy produces complete remission in 85–90% of patients newly diagnosed with ALL, most of these patients will relapse sooner or later.

Salvage chemotherapy, that is, a second round of treatment used with the hope of generating a new round of therapeutic responses, produces remissions in 18–44% of these patients, but these remission periods are short, often between 4 to 5 months. Such periods of remission, while they are occurring, provide an opportunity to implement a second therapy involving bone marrow transplantation (BMT), with the removal by strong chemotherapy of a patient's entire repertoire of immune cells (including the ALL cells) and the replacement of these cells with those coming from a healthy bone marrow donor.

This explains why a treatment was sought that would induce longer-lasting remission periods than the existing chemotherapy protocol, thereby making more BMTs possible. The results, summarized in Figure 16.14B, found the median 7.3-month period of remission achieved by blinatumomab superior to the median 4.6 months survival afforded by chemotherapy and paved the way for blinatumomab to become the first bi-specific T-cell engager to receive FDA approval. This approval provided validation of an entirely novel type of immunotherapy and prompted the entry of a flock of candidate T-cell engagers into the research and development pipeline directed toward treatment of a variety of hematological and solid tumors.

In the aforementioned clinical trial comparing a BiTE with chemotherapy, 61% of the patients receiving the BiTE experienced a serious adverse event (AE) relative to the 45% in the chemotherapy group to which it was compared. These adverse events included cytokine release syndrome (CRS), which is also encountered during CAR T-cell therapy as described earlier. This BiTE therapy also yields a second type of undesired side effect, specifically the depletion of normal B cells, termed B-cell lymphopenia.

Notably, T-cell engager therapies do not require the complex steps that are involved in CAR T-cell therapies, which include the arduous processes of harvesting T-cell populations followed by manipulating and expanding them *ex vivo* prior to re-infusing them into patients. Nonetheless, as seen with almost all anti-cancer therapies including immunotherapies, resistance to BiTE therapy often develops. The primary causes of resistance are predictable. Thus, loss or down-regulation of target antigen display is commonly encountered and, as we read in Section 15.13, is employed by tumor cells in order to evade or escape immune attack. The up-regulation of the PD-1 checkpoint receptor on the surface of the T cells responding to engager therapy can also reduce therapeutic responses. Finally, the phenomenon of T-cell exhaustion, discussed in the next section, can also compromise ongoing T-cell engager immunotherapy. Hence, like other immunotherapies, this novel treatment strategy holds the promise for overcoming shortcomings of existing therapies, but, at the same time, carries its own set of risks and side effects.

OceanofPDF.com

Glossary

salvage chemotherapy
: A round of chemotherapeutic treatment given to a patient who initially responded well to an initial round of chemotherapy but then relapsed.

lymphopenia
: Deficiency of lymphocytes in the circulation. *Also termed* **lymphocytopenia**.

exhaustion
: (adj. **exhausted**) Physiological state of a T cell that has lost many of its normally exercised effector functions; provoking signals include chronic antigen stimulation and prolonged contact with antigen-presenting cells. Less commonly, NK cell exhaustion and macrophage exhaustion.

bispecific T-cell engager
: A re-engineered antibody-derived molecule that simultaneously binds a T cell displaying a T cell-specific cell surface antigen, often CD3, to a second cell, such as a targeted cancer cell that displays a distinct cell surface antigen; such an antibody is used to drive the physical linking and thus juxtaposition of the T cell with the targeted cell.

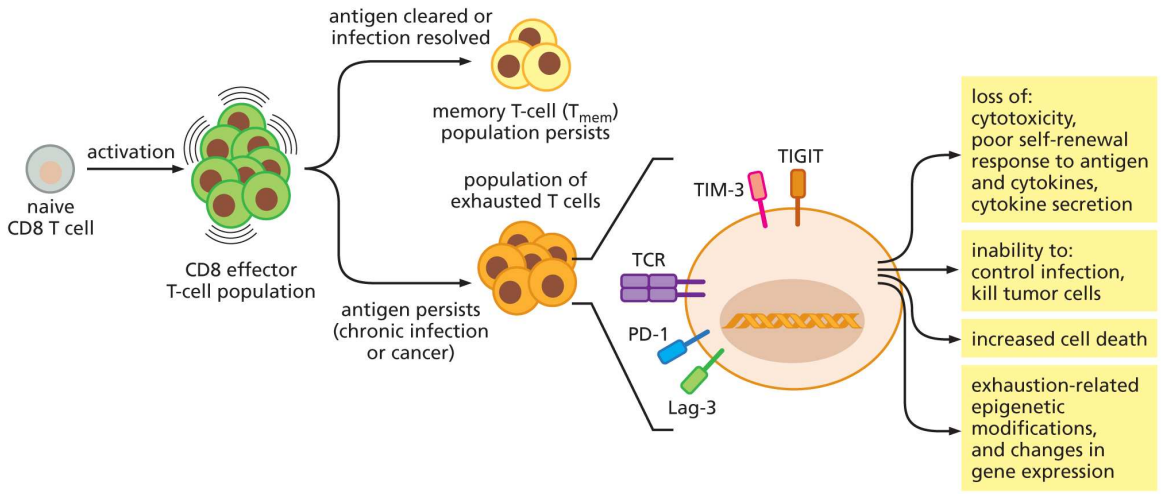
OceanofPDF.com

16.13 T-cell–dependent immunotherapies can be hampered by T-cell exhaustion

The effectiveness of the various types of immunotherapy described here ultimately depends on various regulatory controls that allow T cells, often CD8+ cytotoxic T cells (CTLs), to attack and kill targeted cancer cells. All of these therapies may be ineffective, however, if the CTLs are functionally compromised in one way or another, often by the process that leads to their state of exhaustion. Like the immune checkpoints described above, the T-cell exhaustion response originally evolved as yet another means to protect against the damaging effects on normal tissues generated by chronically activated T-cell populations.

Our current understanding of the controls leading to T-cell exhaustion stems historically from studies in mice of the immune responses following various types of viral infection. Thus, when the infections were rapidly cleared, the populations of CD8 T cells that remained behind were heterogeneous and could be classified into three major subpopulations on the basis of their expression of certain cell surface markers, epigenetic changes, and patterns of gene expression. These three broad groups were effector T cells (T_{eff}), memory T cells (T_{mem}), and exhausted T cells (T_{ex}). Cells belonging to the effector T-cell subpopulation were found to be actively cytotoxic, to secrete IFNγ and other cytokines, to be nonproliferating, and ultimately to undergo cell death. Memory T-cell populations (T_{mem}), in stark contrast, persisted long after the clearance of viral antigens and retained the ability to proliferate in response to a new challenge by the viral antigens that had previously provoked their formation.

The exhausted T cells (T_{ex}) arose under a variety of conditions. Most importantly, initial viral infections that were not successfully cleared could persist as chronic infections. Under such conditions, a T-cell population eventually emerged in which cells exhibited greatly reduced or no effector functions, lost proliferative capacity, and displayed inhibitory receptors such as PD-1. Such T cells were deemed to be “exhausted” and, additionally, were found to have little capacity to self-renew and could not generate T_{mem} populations (**Figure 16.15**).



An Overview of T-cell exhaustion. Activation of a naive C D 8 T-cell leads to the creation of a C D 8 effector T-cell population. If the antigen is cleared or the infection is resolved, a memory T-cell population persists. If, on the other hand, the antigen persists due to chronic infection or cancer, then a population of exhausted T cells arises. These display the T cell receptor on their surface, but also markers such as P D-1, Lag-3, Tim-3, and T I G I T. These cells are characterized by loss of cytokine secretion and cytotoxicity, poor self-renewal response to antigens and cytokines, inability to control infection or kill tumor cells, increased cell death, exhaustion-related epigenetic modifications, and changes in gene expression.

Figure 16.15 Overview of T-cell exhaustion Following activation, T cells may experience different fates depending on the duration of the antigenic stimuli that they receive. When the antigen is presented to the immune system and is cleared, as occurs after immunization via vaccination or after an infection is resolved by the actions of the innate and adaptive immune systems (*above*), some members of the responding T-cell population differentiate into effector T cells, most of which eventually die. Some, however, differentiate into various types of memory T-cell populations, which may survive for protracted periods of time. In contrast, chronic stimulation, which operates in persistent infections and in cancer (*below*), results in protracted stimulation and the eventual differentiation of responding T cells into a state termed “exhaustion.” Exhausted T cells (*lower right*) display one or more inhibitory markers, such as PD-1, Lag-3, Tim-3, and TIGIT, and also show alterations in gene expression and loss of several functions. (Adapted in part from K.E. Pauken and E.J. Wherry, *Cell* 163:1038, 2015. With permission from Elsevier.)

Further research in this area demonstrated that exhausted T-cell populations could be found in humans suffering from HIV infection and in those suffering from chronic hepatitis B or C viral infections; all of these viral infections can persist for years in infected patients and with unabated viral replication. As we now realize, T-cell exhaustion is also an important element of the immune dysfunction that allows tumors to grow out. This state often develops in populations of T cells that have entered into growing tumors and experience chronic stimulation by various tumor antigens. Under these conditions, such T cells are simply unable to control or eliminate tumors and enter into a state of exhaustion. Furthermore, the development of functional exhaustion can compromise the effectiveness of adoptive T-cell transfer (see Section 16.7) and CAR T-cell immunotherapies (**Sidebar 16.11**; see also Section 16.8).

Sidebar 16.11 Exhaustion compromises the effectiveness of ACT and CAR T-cell therapies

Two immunotherapy strategies described earlier—adoptive T-cell transfer and CAR T-cell therapy—involve the *ex vivo* expansion of small populations of T cells to very large numbers during the course of many weeks. Critical to the success of the expansion protocols is the continuous stimulation of T-cell signaling pathways by engagement of the T-cell receptor in the presence of IL-2, the cytokine essential for T-cell proliferation. Although being indispensable for the generation of the large numbers of cells needed for these therapies, such persistent IL-2-driven expansion *ex vivo* can, on its own, force the proliferating T cells into the early stages of exhaustion. This compromises, in turn, the capacity of any subsequently infused T cells or CAR T cells to maintain robust and durable cytotoxic activity against tumor targets. Moreover, such infused cells have lost the ability to generate persisting memory T-cell (T_{mem}) populations that would be capable of future proliferation and the generation of cytotoxic activity in response to the reappearance of cancers after extended periods of clinical remission.

This significant complication of *ex vivo* T-cell expansion has stimulated the exploration of strategies designed to prevent or at least minimize the development of exhaustion. As one example, some of these strategies involve the use of CRISPR-Cas9 (see Sidebar 12.11) to delete from the genomes of proliferating T cells several of the genes specifying transcription factors that are known to play key roles in orchestrating T-cell exhaustion. Also, chronic rather than periodic signaling induces exhaustion, which has suggested the appealing approach of

expanding T-cell populations by periodic cycles of stimulation and stimulus interruption, the latter being termed “rest.” In addition, our increasing understanding of the mechanisms underlying T-cell exhaustion may suggest yet other approaches, including pharmacological ones, for the prevention or reversal of this state.

The PD-1 receptor that operates to enable one type of checkpoint control (see Section 16.9) is also a marker of T-cell exhaustion that appears on responding T cells and on their CAR T-cell counterparts during prolonged antigen stimulation. The development of a fully exhausted state is not inevitable however. Thus, at early stages of T-cell exhaustion, treatment with the anti-PD-1 immune checkpoint inhibitor can halt its development, and previously exhausted T cells can be coaxed back into fully functional states. However, as exhaustion develops further, T cells become increasingly resistant to reversal of exhaustion achieved by interrupting PD-1 signaling, which at this stage has therefore become an ineffective strategy for invigorating various forms of immunotherapy (see Sidebar 16.11).

OceanofPDF.com

16.14 Synopsis and Prospects

Cancer immunotherapy provides an impressive demonstration of the translation of basic preclinical research into effective clinical interventions. As it turned out, most of the immunotherapies described in this chapter and now deployed for the treatment of cancer did not emerge from organized programs of drug discovery directed toward the development of novel cancer treatments. Instead, their origins can be traced to efforts designed to understand the biology of immune responses at the most fundamental level with no preconception of how resulting insights might one day impact clinical medicine.

Adoptive cell transfer (ACT) was initially developed as an experimental technique to determine and study the cell–cell collaborations essential for normal immune responses. Only later was it harnessed to capture a sample of a cancer patient's small population of anti-tumor T cells, expand their numbers *ex vivo*, and return the greatly increased cell population to the donor to treat their cancer. Chimeric antigen receptor (CAR) T-cell protocols arose as a marriage of adoptive cell transfer and the capacity, borrowed from monoclonal antibody technology, to generate antibodies that specifically bound tumor antigens.

Antibody–drug conjugates (ADCs) and bi-specific T-cell engagers (BiTEs) represent yet other offspring of monoclonal antibody technology. ADCs enable the targeting of highly cytotoxic drugs to tumors; this technology was designed to avoid the extensive systemic toxicity that often accompanies administration of these agents. BiTEs play a very different role, bringing T cells together with tumor cells that they would not otherwise engage. And finally, we note that fundamental research on how immune function is regulated has led to the truly revolutionary therapies based on immune checkpoint blockade (ICB) that have already yielded two Nobel Prizes!

But all of this, impressive as it is, should be viewed as no more than a beginning, representing very promising early steps toward the goal of

effective management of cancers. The challenge is to find ways to improve immunotherapies so that, for many cases of cancer, cure becomes an expected outcome rather than an aspirational goal that is achieved only infrequently. At present, research focused on improving existing immunotherapies is rapidly evolving and future trajectories are already apparent as described below. Also, in light of the rapid progress of immunotherapy over the past generation, it would be surprising if existing treatment strategies were not joined in the near future by some entirely novel and entirely unanticipated ones.

Many of the existing cancer immunotherapies depend on antibodies or antibody-derived binding sites employed to direct immune attacks on tumor cells displaying tumor-associated antigens (TAAs). Unmodified antibodies, antibody–drug conjugates, CAR T cells, and bi-specific T-cell engagers all target antigens that are not exclusively found on tumor cells but instead are shared with certain normal cells. Consequently, collateral attacks on normal cells are inevitable, yielding side-effect toxicities that can prove to be life-threatening. This consideration helps to explain why, for example, antibody-driven therapies to treat hematologic cancers are restricted at present to lymphomas of the B-cell lineage. Although normal B cells are killed together with targeted lymphoma and leukemia cells, the B-cell lymphopenia that develops is manageable, and the affected normal cell population recovers once therapy is completed.

The problems associated with targeting of tumor-associated antigens (TAAs; Section 15.8) persist simply because it is impossible or unfeasible to identify tumor-specific antigens (TSAs) in many tumors. These problems also hobble the ADC, CAR T-cell, and bi-specific antibody treatments employed to treat carcinomas. Although these tumors create ~80% of cancer-associated mortality, immunotherapies targeting their TAAs inevitably affect the cells forming normal epithelia. In many cases, the resulting collateral side effects of attacks on these normal tissues, causing immune-mediated destruction of critical tissues, are intolerable, generating significant morbidity and even life-threatening losses of normal tissue functions. Even if not life-threatening, the necessity of limiting collateral damage to normal tissues is likely to compromise dosage levels and, in

many cases, forces withdrawal of the therapy before its treatment objectives have been fully realized.

Nevertheless, despite these inherent liabilities, antibodies and ADCs (antibody–drug conjugates) have proven useful for the treatment of certain subtypes of breast cancers (see Section 16.6). Progress in extending cytotoxic antibody therapies to the treatment of additional breast cancer subtypes will depend on identifying additional TAAs, such as trophoblast cell surface antigen 2 (Trop2); even now, anti-Trop2-mediated attack by the ADC sacituzumab govitecan is used to treat some triple-negative breast cancers. Identification of alternative target antigens displayed by the cells of normal tissues but significantly upregulated by tumor cells will enable extension of these therapies to the treatment of a wider variety of carcinomas and other solid tumors.

The power of antibodies and ADCs to selectively target cells that display their cognate antigen creates a vulnerability that is likely, sooner or later, to render each of these therapies ineffective. Thus, as we have read time and again, antigen-guided attacks on tumor cells select for members of tumor cell populations that contrive to reduce or cease display of the targeted antigens, rendering them unresponsive to the immunotherapy being applied. In principle, application of a bi-specific antibody targeting two distinct TAAs displayed concomitantly on the surface of individual tumor cells should trigger attacks of the type that are not so easily evaded by loss of one of the two targeted TAAs. This, in turn, should avoid or significantly delay the development of therapeutic resistance.

Currently employed clinical practice yields other instructive examples of future therapeutic strategies. For instance, rather than using an antibody as a monotherapy, current clinical practice for the treatment of some B-cell lymphomas combines antibodies that are directly cytotoxic with chemotherapies, which act through mechanistically unrelated ways. The design of such two-pronged attacks on these tumors is motivated by a similar consideration, that is, the low probability that lymphoma cells can concomitantly develop resistance to a chemotherapeutic agent applied together with antibody-driven attacks on one or more B-cell surface antigens.

Antigen loss is also a major cause of the acquired resistance to CAR T-cell therapy. One study described the clinical courses of large B-cell leukemia (LBCL) in 16 patients being treated with anti-CD19–CAR T-cell therapy. Eleven of these patients eventually showed down-regulation or complete loss of CD19 display. In the near future, this problem of immunoevasion will be approached in either of two ways. One may involve the development of a collection of monospecific CAR T cells, each one recognizing a distinct antigen, with infusion of these cell lines either together or sequentially, one after the other. An attractive alternative to this cumbersome approach involves construction of a single CAR T-cell line bearing not one but a repertoire of multiple distinct CARs, each specific for a different tumor antigen (**Sidebar 16.12**).

Sidebar 16.12 Initial attempts at using CAR T cells to target multiple tumor-associated antigens

The observation that many B-cell malignancies that express CD19 also display the CD22 antigen has already inspired the construction of CAR T cells with dual specificity, bearing one CAR capable of recognizing CD19 and a second CAR specific for CD22. Initial clinical findings in patients of lymphoma patients infused with such CD19–22 CAR T cells showed that the dual-specificity CAR T cells induced various degrees of remission in a patient cohort and, in a handful of these patients, PET scans revealed dramatic reductions of tumor masses. Furthermore, some of the treated patients exhibited clear evidence of the persistence of populations of the dual-specificity CAR T cells, suggesting the possibility of launching future attacks on persisting or returning tumor cell populations displaying the targeted antigens. However, though an encouraging beginning, the efficacy of these dual-specificity CAR T cells did not actually exceed that of monospecific anti-CD19–CAR T therapies already in clinical use. Still, even now we can anticipate the development of CAR T-cell therapies involving their further modification from functional monospecificity to multispecificity and resulting substantial increases in therapeutic efficacy.

Nonetheless, even with the adoption of therapeutic strategies that enable CAR T cells to anticipate and overcome eventual evasion arising from antigen loss, the creation of these cells requires an elaborate technology involving harvest of each patient's T cells, their conversion to CAR-expressing cells, and the reinfusion of resulting CAR T cells into the donor. In addition, this immunotherapeutic technology, at least as presently configured, is encumbered by a number of additional significant problems.

Thus, in addition to their forced display of chimeric antigen receptors, CAR T cells retain their complement of preexisting conventional TCRs. The ongoing display of these indigenous TCRs imposes limits on the application of CAR T-cell therapies, simply because these receptors continue to recognize allogeneic MHC complexes as foreign. As a direct consequence, when CAR T cells carrying these TCRs are infused into allogeneic recipients, the cells may attack a broad array of these recipients' tissues, often resulting in life-threatening graft-versus-host (GVH) reactions. For this reason, at least at present, each batch of infused CAR T cells represents, in effect, a personalized drug, offering great possible therapeutic benefit to a syngeneic recipient while, at the same time, triggering potentially lethal responses in allogeneic recipients. In addition, the assembly of CAR T-cell populations requires periods of at least 2–3 weeks between harvest and reinfusion, leading to significant delays in the initiation of a patient's treatment. Finally, quite often a cancer patient's physical condition may make it difficult to harvest sufficient numbers of T cells for CAR T-cell preparation.

A promising alternative to CAR T cells is poised to emerge. Natural killer (NK) cells have been engineered to express chimeric antigen receptors conferring on these innate immune cells a predefined specificity for a particular tumor antigen. As we read previously (Section 15.9), NK cells are capable of launching a variety of potent cytotoxic attacks on the cells they target. Importantly, unlike their CAR T-cell counterparts, the initially unmodified NK cells lack preexisting TCRs and are therefore incapable of mounting inadvertent GVH reactions. For these reasons, CAR-NK cells can be generated from an allogenic donor and deployed in many different allogenic recipients without the danger of life-threatening GVH reactions.

Moreover, NK cells, are already known to mount stronger attacks against allogeneic tumors than against syngeneic ones.

In fact, CAR-NK cells can be generated from NK cells retrieved from umbilical cord blood, thereby leveraging the availability of relatively abundant frozen stores of cord blood cells to prepare CAR-NK cells for use in allogeneic recipients. Preliminary studies have already shown that a single unit of umbilical cord blood yields sufficient NK cells to prepare to enough CAR-NK cells for treating several patients. In the longer term, if proven efficacious and safe, previously prepared batches of CAR-NK cells could provide an “off the shelf” therapy, being instantly available, less expensive, and available to a wider range of patients than the conventional CAR T-cell treatments currently available.

Indeed, anti-CD19–specific CAR-NK cells prepared from frozen cord blood-derived NK cells have already been employed in a clinical trial that enrolled patients with relapsed or treatment-refractory CD19-positive non-Hodgkin’s lymphoma or chronic lymphocytic leukemia. In this early-stage clinical trial, 7 of 11 members of the patient group showed elimination of detectable tumor cells at 14 months after CAR-NK therapy. Of note, all of these patients were allogenic with respect to the CAR-NK preparation administered. In addition, cytokine release syndrome (CRS), which is often observed as a side effect of existing CAR T-cell therapies, was not observed in this study. If these striking initial clinical studies are sustained and reinforced in larger trials, CAR-NK cells will become a highly useful addition to the repertoire of adoptive cell transfer therapies for the treatment of cancer.

All of the adoptive cell transfer therapies cited here—adoptive T-cell transfer, CAR T-cell, and CAR-NK therapies—as well as the bi-specific T-cell engager (BiTE) therapy, involve continuous functional activation of the introduced cells and their attendant proliferation. This suggests that all of these therapies will eventually be compromised by the functional exhaustion of the introduced immunocytes, indeed an outcome that has already been observed. This suggests an urgent need to develop strategies for preventing, damping, or reversing exhaustion in both T cells and NK cells, and in their modified derivatives.

In the arena of the ICI treatments described here, involving both CTLA-4 and PD-1 strategies (as described in Section 16.9), further improvements are also desperately needed: both treatments are already in widespread clinical use even though their demonstrated utility is actually limited to a relatively small subset of the tumors encountered in the oncology clinic. Moreover, in the years since the development of the CTLA-4 and PD-1 ICIs, a number of other similarly acting immune checkpoints have been discovered (see Table 16.5), several of which appear promising in terms of their potential to generate clinically useful immunotherapies. Nonetheless, it is already apparent that none of these will be sufficiently powerful on its own to be used as a monotherapy. Instead, echoing the theme regularly encountered in cancer immunotherapy and chemotherapy, they will most likely find roles as components of combination therapies.

Beyond combination therapy, as more has been learned about the dynamics of immune checkpoint blockades, appreciation has grown for the complexity of the multiple host and environmental factors that influence responses to ICIs. Some of these factors are discussed in **Supplementary Sidebar 16.2**.

To summarize, it is clear that much of contemporary cancer research is influenced by the realization that an in-depth understanding of initial cancer pathogenesis (as described in Chapter 11) and the development of improved treatments of existing tumors (as described in this chapter and Chapter 17) will depend on elucidating and exploiting the formidable powers of the immune system. At the same time, development of novel immunotherapies is occurring in the face of an increasing awareness that the development of non-immune-based, truly effective anti-cancer therapeutics has become increasingly challenging. Together, these trends explain the explosive increase in the number of anti-cancer immunotherapies that are currently under development and will surely be introduced into clinical practice in the years to come.

OceanofPDF.com

Key concepts

- Most cancer immunotherapies fall into one of three categories: vaccination against tumor cells and oncogenic microbes; passive immunization via administration of anti-tumor cells or antibodies; and release of immunosuppressive mechanisms, notably those imposed by immune checkpoints.
- Prophylactic cancer vaccines prevent infection by microbial agents that directly or indirectly cause cancer, thereby lowering the incidence of the cancers induced by these agents. Vaccination against Hepatitis B virus (HBV) prevents HBV-induced liver cancer and human polyoma virus (HPV) vaccines prevent most cervical cancer.
- Therapeutic cancer vaccines stimulate the immune system to make adaptive immune responses against tumors that have already established themselves in the body, arresting the growth of these tumors and ultimately rejecting them.
- Passive immunization by administration of antibodies against tumor antigens borne by a patient’s tumor can kill tumor cells in a variety of ways, many of them involving recruitment of cells of the innate immune system.
- Antibody drug conjugates (ADCs) combine the powers of antibody-mediated passive immunization with antibody-guided delivery of highly potent cytopathic drugs.
- Passive immunization can also involve capturing cells of a patient’s immune system, amplifying, and in some cases modifying them, and then infusing them back into the patient. This process is called adoptive cell transfer (ACT).
- CAR T-cell therapy is a form of ACT that is already in widespread use. In CAR T cells, the antigen recognition function of the T-cell receptor is assumed by an engineered chimeric antigen receptor (CAR), a single molecule that incorporates specific antigen recognition, and that has the capacity to trigger T-cell activation and the generation of T-cell proliferation and survival signals.
- Immune checkpoints normally provide essential homeostatic negative feedback controls necessary to prevent excessive inflammation and

destructive autoimmune responses. However, these essential homeostatic controls can dampen or prevent strong anti-tumor responses.

- Immune checkpoint inhibition manipulates the behavior of immune cells in ways that increase the likelihood and potency of their anti-tumor responses. Monoclonal antibodies that interfere with either the CTLA4:CD80/86 or the PD-1:PD-L1/2 axis have proven useful for the treatment of melanoma and a variety of other cancers.
- Bi-specific antibodies (and antibody-like molecules) constructed to simultaneously bind to two cells displaying different cell surface antigens, bring cells that would not otherwise closely engage, into sustained physical contact with each other. A bi-specific antibody, known as a bi-specific T- cell engager (BiTE), can link a T cell to another cell, such as a tumor cell. Such forced juxtaposition of a T cell with a second cell can result in the T-cell-mediated death of the second cell, such as a targeted cancer cell.
- T-cell-mediated therapies depend on sustained T-cell activation but can be compromised by T-cell exhaustion. Therefore, it is important to develop a deeper understanding of this phenomenon in order to make activation-dependent T-cell-mediated cancer therapies more enduring and thus more effective.

Thought Questions

1. Initial treatment of a patient’s cancer with anti-PD-1 was ineffective. Following irradiation, the patient's tumor showed modest shrinkage and then resumed growth. However, a second course of treatment with anti-PD-1 resulted in regression of tumor growth. Offer reasonable hypotheses for: (a) why treatment with anti-PD-1 was initially ineffective and (b) why anti-PD-1 may have been effective after radiation therapy.
2. CAR T cells specific for CD20 were generated from T cells harvested from a lymphoma patient, frozen, and subsequently used in a successful treatment of the patient’s cancer. However, several frozen ampoules of this effective CAR T-cell preparation were not used. An enthusiastic oncology resident suggested that these surplus CAR T cells could be used to treat future lymphoma patients whose profile of surface antigens indicated they might benefit from treatment with anti-CD20 CAR T cells. A second oncology resident, who had paid attention during her immunology rotation, explained to her colleague why this was not a good idea. What did she say?
3. Distinguish between prophylactic and therapeutic cancer vaccination. What etiology is shared by cancers that can be prevented by prophylactic immunization? Briefly outline the advantages offered by therapeutic cancer vaccination and suggest the form such vaccines might take.
4. Antibodies have become mainstays of cancer immunotherapy. Some anti-tumor antibodies directly kill tumor cells. Other highly effective antibodies have no direct cytotoxic effect on tumor cells. How does one class of molecules play such different roles in cancer therapy?
5. What advantages, if any, do bi-specific T-cell engagers have over CAR T cells for the treatment of cancer? What feature of CAR T cells might give them an advantage over these bi-specific agents?
6. Adoptive T-cell transfer has shown a capacity to treat a wider variety of cancers than CAR T cells or BiTEs. What is the basis of the ability of this approach to target a particularly broad spectrum of cancers? Given its demonstrated ability to target many different kinds of cancer, why is it not more widely practiced?

7. Antibody–drug conjugates (ADCs) are highly effective anti-tumor agents. Briefly identify the many ways in which an ADC can kill or induce the death of its target cell. Given their many strengths, identify a strategy of evasion used by some tumor cells to escape killing by antibodies and CAR T cells that also allows them to evade killing by ADCs. Suggest how you might create an ADC that would be less susceptible to this commonly adopted strategy of escape from immune-mediated killing.
8. T-cell exhaustion is a well-established immunological phenomenon and can blunt the therapeutic effects of adoptive cell transfer strategies, bi-specific T-cell engagers, and release of checkpoint blockade by ICIs. Although these are very different approaches, why are all of them susceptible to loss of efficacy because of T-cell exhaustion?

Supplementary Sidebars

Supplementary Sidebar 16.1 How to make monoclonal antibodies

Antibodies generated during a particular immune response are a heterogeneous population of molecules with different antigen-recognizing specificities. This heterogeneity arises because the antibodies formed following immunization with a given antigen are produced from a diverse population of B cells and derived plasma cells, and each responding plasma cell produces its own version of an antibody able to bind in a specific manner the immunizing antigen. Although useful for certain applications, each batch of antibodies produced by exposure to an antigen contains not only a heterogeneous collection of these antibodies but also one that is irreproducible from one batch to another.

In an ideal world, one should be able to isolate individual antibody-producing B cells from, for example, the spleen of an antigen-immunized mouse, propagate these cells *in vitro*, and expand the descendants of each of these explanted cells into a large, monoclonal population. Because the cells in each of these resulting monoclonal populations would be genetically identical to one another, each population should secrete into a culture medium a uniform homogeneous population of antibody molecules, which in principle could be tested for its ability to recognize and bind an antigen of interest.

The biological reality however renders this scheme unworkable. It has been and continues to be impossible to explant individual cells from the spleen of a mouse and propagate them *ex vivo* for any period of time, simply because these cells have not been immortalized and are unfit to proliferate in appropriate culture media.

This problem was addressed and solved in 1975 by Georges Köhler and Cesar Milstein, who invented a technique for immortalizing individual antibody-producing B cells, which, in turn, enabled their expansion *ex vivo.* Each of the resulting expanded monoclonal cell populations should produce a homogeneous population of antibody molecules that are identical to one another and possess identical affinity and specificity for an antigen.

Rather than introducing an immortalizing gene or set of genes into a set of spleen-derived B cells, Köhler and Milstein determined that a more effective immortalizing strategy would be to fuse each of a large population of spleen-derived B cells with a myeloma cell, that is, a neoplastic cell that naturally possesses an immortalized phenotype as a consequence of the multi-step progression that led previously to the outgrowth of the myeloma in the first place.

Myeloma is a tumor of plasma cells, which represent the cells at the antibody-producing, terminal stage of B cell differentiation. Like virtually all human neoplasias, each myeloma arises from the transformation of a single plasma cell and is therefore a monoclonal cell population. Hence all of the antibodies secreted by all of the cells composing a patient's population of myeloma cells are encoded by identical immunoglobulin genes, have identical amino acid sequences, and therefore exhibit identical antigen specificities and affinities. The presence of the disease is signaled by the expression of a single dominant antibody species in the blood rather than a broad spectrum of such antibodies that is normally present, as resolved and visualized by electrophoresis (see **Supplementary Sidebar 2.5**). Accordingly, each myeloma tumor cell population represents a monoclonal population that is derived from a common cell-of-origin and produces an antibody species that happens to have been produced by the cell-of-origin that acquired the somatic mutations that transformed it to a neoplastic state. Accordingly, while representing a monoclonal population, the investigator can exert no control over the antigen specificity of the antibody secreted by any given myeloma. The antibody molecules produced by the cells of a myeloma are directed against an unknown antigen that reflects the history of the founding cell-of-origin of the myeloma tumor cell population. In fact, the individual myeloma cells of such a population possess three important features of interest. First, the antibody-encoding gene developed by its cell-of-origin. Second, the oncogene(s) that allowed these cells to become tumorigenic and thus immortalized. Third, myelomas arise from plasma cells, the only stage of B cell differentiation that is permissive for the synthesis and secretion of large amounts of antibody. The existing antibody-encoding properties of the myeloma cell are irrelevant to what follows.

Köhler and Milstein's key and enabling insight was the realization that they could take a large population of B cells from the spleen of a mouse that had been immunized with an antigen of interest and, ideally, fuse each of these cells individually to a myeloma cell. This fusion would provide each of the B cells with an immortalizing gene (or set of genes), allowing it to proliferate indefinitely in culture with a retention of its previously developed antibody-producing

powers. A few years later, the use of myeloma or myeloma-derived cell lines that had lost the capacity to produce endogenous antibody chains was a major technical advance that removed the complication of unwanted production of myeloma immunoglobulins (see Figure 7.1).

The B cells used in these fusions exhibit the expected heterogeneity of B cells normally present in, for example, the spleen or other secondary lymphoid tissues, such as lymph nodes. Because the B cells are prepared from a mouse that has been recently immunized with specific antigen of interest, a significant percentage of the B cells prepared from the spleen of this mouse will be B cells that have developed antibody responses against the immunizing antigens. Thus, among several hundred randomly chosen B cells from the spleen of the recently immunized animal, there will likely be dozens that have developed an antibody against the antigen of interest. Like the overall population of B cells in the spleen, even this smaller population making antibodies of interest will exhibit a degree of heterogeneity. The strategy thereafter would be to immortalize each of these B cells separately and identify which of these produces an antibody of sufficient antigen affinity (tight binding) and specificity.

When the two cells are fused together (see Figure 7.1), the resulting hybrid cell that is formed when a normal B cell fuses with a myeloma cell is termed a *hybridoma*. As described above, such a cell retains the ability of the normal B-cell parent to make an antibody specific for the immunizing antigen and retains the myeloma parent's capacity for indefinite survival and proliferation in culture, that is, the trait of replicative immortality as described in Chapter 10.

Because each hybridoma represents a monoclonal cell population, being the descendants of a single B cell partner, the antibodies that all of the cells in this population produce are identical throughout their structure, including their antigen-binding sites. Such antibodies are called *monoclonal antibodies* (moAbs).

In more detail, splenocytes, including large numbers of B cells, are isolated from a mouse that has been immunized, often repeatedly, with an antigen of interest. A population of such splenocytes is then fused, each individually, with cells from a suitable myeloma cell line, leading to a large population of hybrid cells. (Successfully fused cells can be isolated using a drug selection protocol designed to eliminate all unfused cells.) Such hybrid cells that grow out after a period of time are then introduced individually into an array of microtiter wells at low seeding density in order to ensure that each well receives at most only a single hybrid cell. The cells in these wells are then cultured for a period of some days to

ensure that they can secrete into the supernatant medium present in each well the antibodies that they should be capable of producing. The media of microtiter wells that carry antibody against the antigen of interest are then identified and the hybrid cells that are present in these microtiter wells are retrieved and expanded *ex vivo*, yielding a population of hybridoma cells that encodes a secreted immunoglobulin and can be propagated indefinitely in culture and expanded into large culture vessels for the essentially unlimited production of the monoclonal antibody.

Today, however, a newer technology is employed to produce antibodies that are to be used for therapeutic applications. These newer types of moAbs have amino acid sequences that are essentially fully human and are derived in one of three ways: phage display technologies, the use of recombinant DNA technology to clone and express antibody genes from human B lineage cells, and immunization of transgenic animals carrying human immunoglobulin genes, as described below.

Independent of the specific protocols that are followed, the advent of technologies for the derivation of monoclonal antibodies and the subsequent development of the capacity to produce them in unlimited amounts has been revolutionary for preclinical research and clinical therapeutic applications. Monoclonal antibodies are now the standard reagents for the performance of serological assays, for diagnostic histology and flow cytometry, and for many therapeutic applications, explaining why a large and growing number of them are finding applications in oncology. Monoclonal antibodies (moAbs) used for investigational or diagnostic purposes are derived by producing hybridomas from murine sources, that is, B cells from the spleens of immunized mice as described above (**Figure S16.1**).

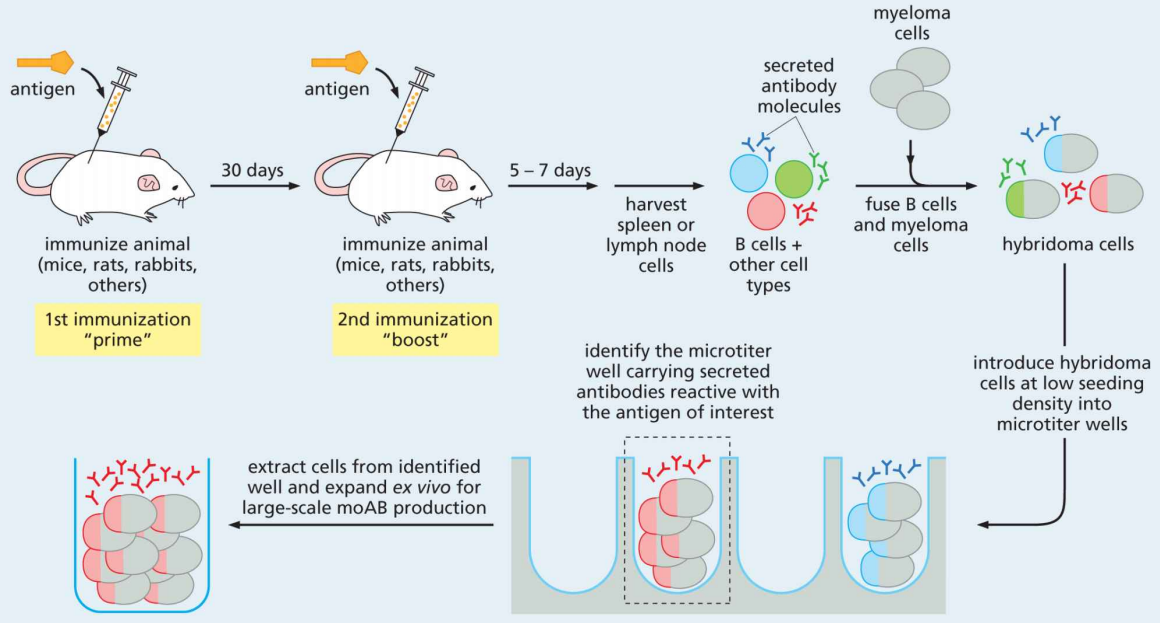

Figure S16.1 How to make monoclonal antibodies The antigen against which monoclonal antibodies are to be raised is repeatedly administered to mice or some other species at intervals suitable for raising an antibody response. The initial immunization is known as priming and subsequent administrations of antigen are called boosts. Three to five days after the last boost, the spleen or a few lymph nodes are collected and their immunocytes are harvested and fused to a suitable myeloma cell line, the cells of which have lost the ability to make antibodies. The fusion of individual B cells with myeloma cells yields hybridoma cells. Drug selection kills unfused myeloma cells and unfused B cells are incapable of extended proliferation in culture. The heterogeneous population of hybridoma cells is diluted and added to the wells of microtiter dishes at seeding densities low enough to ensure that each well receives no more than one hybridoma cell. After a period of growth, a sample of the supernatant from each of the monoclonal cultures that emerge is collected and added to the wells of assay plates that have been coated with the target antigen. After a suitable period of incubation, the plates are thoroughly washed and assayed for antibody binding, usually by a chromogenic ELISA-type assay. (Adapted in part from https:mblbio.com/bio/g/support/method/antibody-production.html.)

Use of phage display to make antibodies In a technique for producing antibody-like molecules, large collections of gene sequences encoding the antigen-binding variable (V) domains of antibodies are individually fused to genes encoding the

coat protein of a bacteriophage. Bacteriophages containing such gene fusions are used to infect bacteria. The resulting progeny phage particles have coats that express the antibody-like fusion protein, with the antigen-binding domain displayed on the outside of the bacteriophage virions. A collection of recombinant phages, each displaying a distinct antigen-binding domain on the surface, is known as a *phage display library*. In much the same way that antibodies specific for a particular antigen can be isolated from a complex mixture by affinity chromatography, phages expressing antigen-binding domains specific for a particular antigen can be isolated by selecting the phages in the library that bind specifically to that antigen, which had been expressed as a recombinant protein and immobilized on one or another solid matrix. The few phage particles that bind to the matrix via their linked antigen-binding domain are eluted from the matrix, recovered, and used to infect fresh bacteria. Each phage isolated in this way will produce a monoclonal antigen-binding particle analogous to a monoclonal antibody. The genes encoding the antigen-binding site, which are unique to each phage, can then be recovered from the phage DNA by recombinant DNA procedures and used to assemble genes specifying a complete antibody molecule by joining these genes to segments of immunoglobulin genes that encode the constant (C) domains of an antibody molecule. When these reconstructed complete antibody genes are introduced into a suitable host-cell line, such as the non-antibody-producing myeloma cell variants mentioned above, and used for making moAbs, the transfected cells can secrete antibodies with all of the desirable characteristics of monoclonal antibodies produced from hybridomas, including the homogeneity of the population of secreted antibody molecules.

If most of the residues of the resulting antibody molecules derive from human sources, then the resulting antibody molecules themselves will not provoke an anti-moAb response in a human patient, which would result in the effective neutralization of this antibody by the recipient's immune system. (Conversely, the use of mouse-derived sequences in the reconstructed antibody molecules will indeed provoke an undesired response because the patient's immune system is unlikely to be tolerant of foreign antigens, that is, those of nonhuman origin.)

Generation of human monoclonal antibodies from human B-cell donors In certain cases, human monoclonal antibodies can be made by cloning the rearranged antibody heavy- and light-chain gene sequences from B cells isolated from the peripheral blood of individuals. Individual cells of the B-cell lineage that display antibodies specific for a given antigen can be identified by flow cytometry (FACS) and isolated by cell-sorting technology as single cells.

Thereafter, single-cell DNA sequencing of the genomes of such cells makes it possible to identify the rearranged heavy- and light-chain variable region sequences encoding human antibodies of the desired specificity. Once captured, these sequences are cloned into expression vectors designed to incorporate them into generic human constant (C) region constructs encoding both the light and heavy constant regions. Transfection of these expression vectors into an appropriate mammalian cell line allows production of monoclonal antibody molecules assembled entirely from human sequences and exhibits the desired antigen-recognizing specificity. As described above, such human moAbs can be used therapeutically because they will not provoke an anti-moAb response, as described above.

Generation of monoclonal antibodies from transgenic animals Transgenic animals, largely mice, have been produced in which the resident genomic regions encoding murine immunoglobulin genes have been entirely replaced by human equivalents, that is, the corresponding orthologous sequences present in the human genome. Once again, this strategy is used to avoid the isolation of antibody-encoding genes of mouse origin, the products of which could provoke an anti-murine antibody response in human recipients. When immunized, such human immunoglobulin-expressing transgenic mice produce human antibodies instead of murine ones. Consequently, it is possible to immunize these mice with any desired antigen and to use hybridoma technology (see Figure S16.1) to produce hybridomas that secrete monoclonal human antibodies against the target antigen. Human immunoglobulin transgenic mice are now widely used to derive monoclonal human antibodies for a broad variety of therapeutic applications.

Supplementary Sidebar 16.2 Indicators of success or failure of immune checkpoint blockade therapies

Infiltration of a tumor by CD8+ T cells is widely viewed as a parameter that reliably predicts its favorable clinical responses to immune checkpoint inhibitor (ICI) therapy. Furthermore, the determination that the infiltrating population of CD8+ T cells displays a diverse repertoire of T-cell receptors (TCRs) provides an additional prognostic indicator of a favorable response. Thus, the more diverse the antigen-recognizing domains of these receptors are within a patient’s tumor-infiltrating T-cell populations, the greater the likelihood that certain CD8+ CTLs

will recognize cognate antigens within a tumor and proceed to kill cancer cells. In more detail, T cells can be isolated from the blood of cancer patients and the diversity of the antigen-recognizing domains of their TCRs can be judged by high-throughput sequencing analyses of the genomic segments encoding these domains, yielding a direct metric of TCR diversity, including that of the TCRs expressed by tumor-infiltrating T cells. Indeed, this metric predicts future responses to ICB and reveals whether extensive TCR diversity already exists at baseline (that is, before ICI treatment) or after ICI therapy has been initiated.

The nature of the antigens developed by tumor cells is also critical to determining the nature of eventual immune responses. Thus, to step back a bit, higher frequencies of somatic mutations that have been accumulated in the cancer cell genome during the course of tumor formation provide a higher abundance and richer diversity of neoantigens, thereby increasing the potential for immune recognition (see Section 15.8). Such elevated antigen diversity is often reflected in the finding that tumors with higher tumor mutational burdens (TMBs) are associated with T cells exhibiting greater TCR diversity. This implies, in turn, that many of the individual neoantigens created by somatic mutations can evoke the development of corresponding highly specific TCRs.

Indeed, high TMB has been associated with better responses to either anti-CTLA-4 or anti-PD-1 across a broad spectrum of cancers. Furthermore, the specific mutational mechanisms responsible for the elevation of the TMB (see Sections 12.4 and 12.5) do not actually appear to be important. Thus, tumors that acquire hundreds, even thousands of mutations as a consequence of UV exposure, as is true of many melanomas, and tumors that acquire mutations through inhaled mutagenic carcinogens, as is the case for smokers who develop non-small-cell lung carcinomas, are indeed more responsive to ICIs.

Most unexpectedly, the composition of patient microbiomes may significantly influence responses to ICIs. For example, mouse studies have demonstrated that the presence of certain bacterial species in the gut promoted therapeutic responses to anti-CTLA-4 immunotherapy, whereas others promoted responses to anti-PD-1 therapy. In addition, a clinical study of patients with urothelial carcinoma, renal cell carcinoma, and non-small-cell lung cancer showed that antibiotic treatment during the course of anti-PD-1 immunotherapy was negatively correlated with patient responses to ICI immunotherapy. This suggested that somehow immunostimulatory effects were being conferred by the presence of certain commensal bacterial species and that these species and the beneficial effects on the host immune responses (including those conferred by ICI therapies) were

being eliminated by the use of antibiotics. These observations suggest that analyses of intestinal microbiota might one day provide useful indicators of those patients who are likely to respond to ICI immunotherapy and those who are not. In fact, certain microbiomes contain microbial species that are associated with poor responsiveness to checkpoint-mediated immunotherapy. These microbiome-based indicators and those cited in **Figure S16.2** are helpful but inadequate predictors of ICB response. At present, we lack reliable predictors of clinical responses for ~80% of the patients being treated with various ICB therapies.

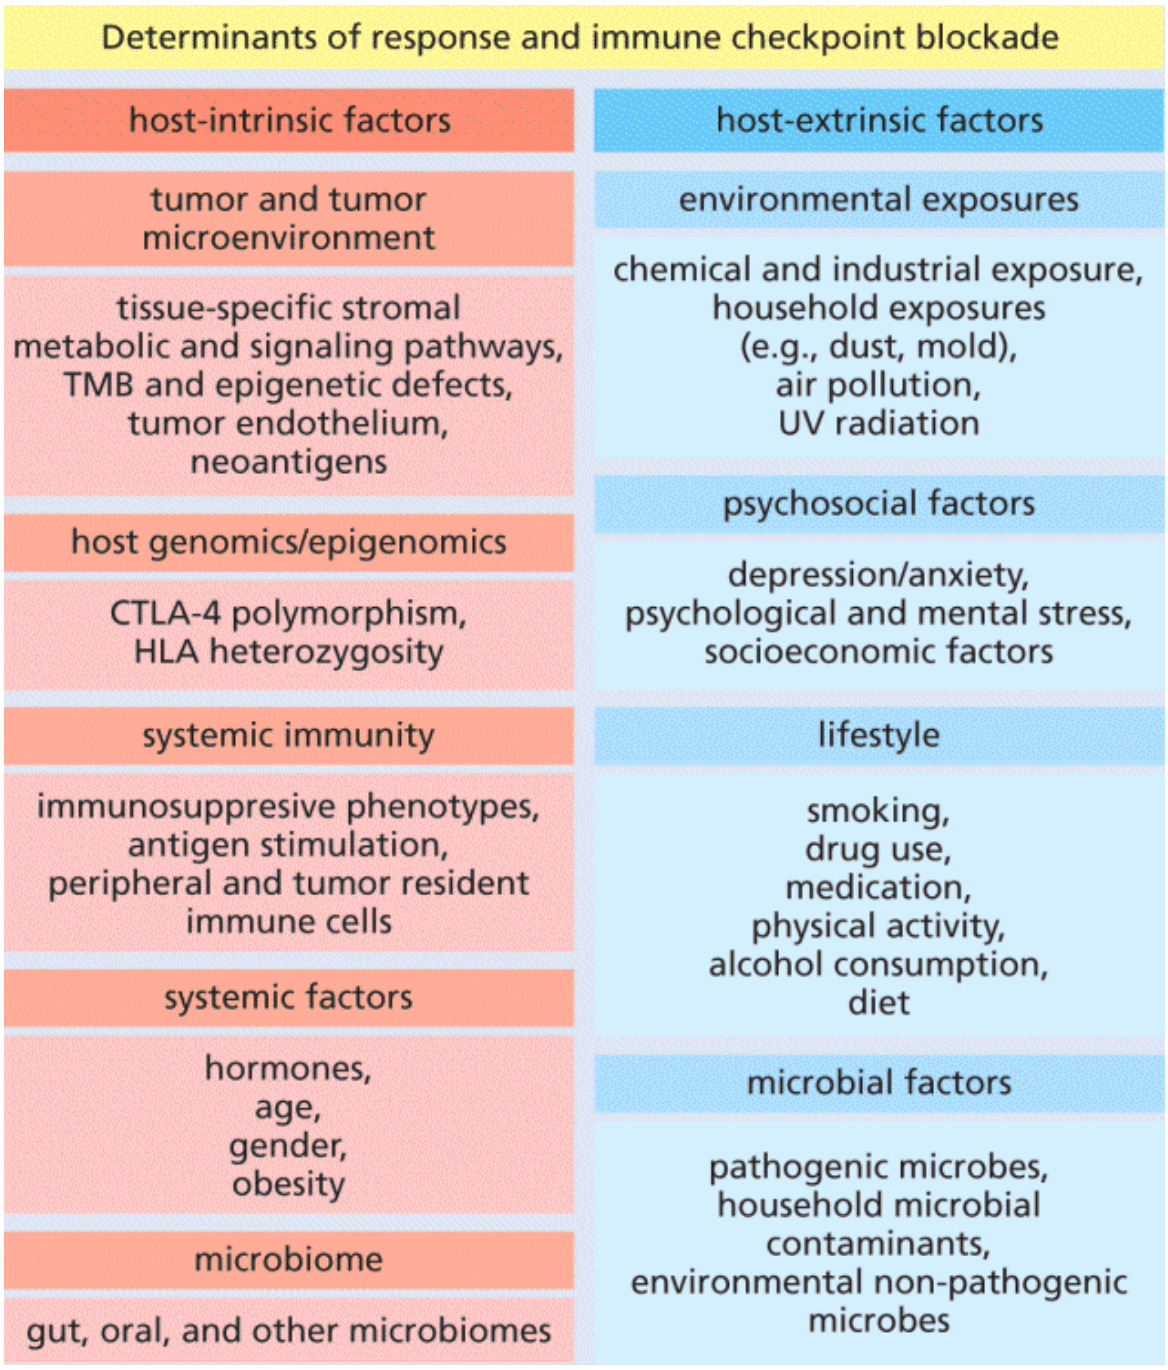

Figure S16.2 Factors governing clinical responses to checkpoint blockade inhibition A variety of host-intrinsic and host-extrinsic factors influence the response to treatment with immune checkpoint inhibitors. OceanofPDF.com

Glossary

splenocyte
: A leukocyte isolated from the spleen, which may belong to B or T cell populations as well as myeloid-derived populations, such as macrophages and dendritic cells.

affinity chromatography
: Procedure for enriching from a complex mixture of biological molecules the subpopulation of biomolecules that binds specifically to a cognate ligand or molecular binding partner, the latter being immobilized on a solid matrix. Molecules that are retained on the matrix, in contrast to the bulk population of molecules that are not, can subsequently be eluted from the matrix and prepared for various additional enrichment or analytic techniques.

tumor mutational burden
: The total number of mutations found in the genomic DNA of tumor sample, often presented as number per haploid genome or per megabase of genomic DNA.

commensal
: Referring to a long-term interaction between two organisms, such as gastrointestinal bacteria and their mammalian hosts, which reflects symbiosis between the organisms and may accrue to the benefit of both of them.

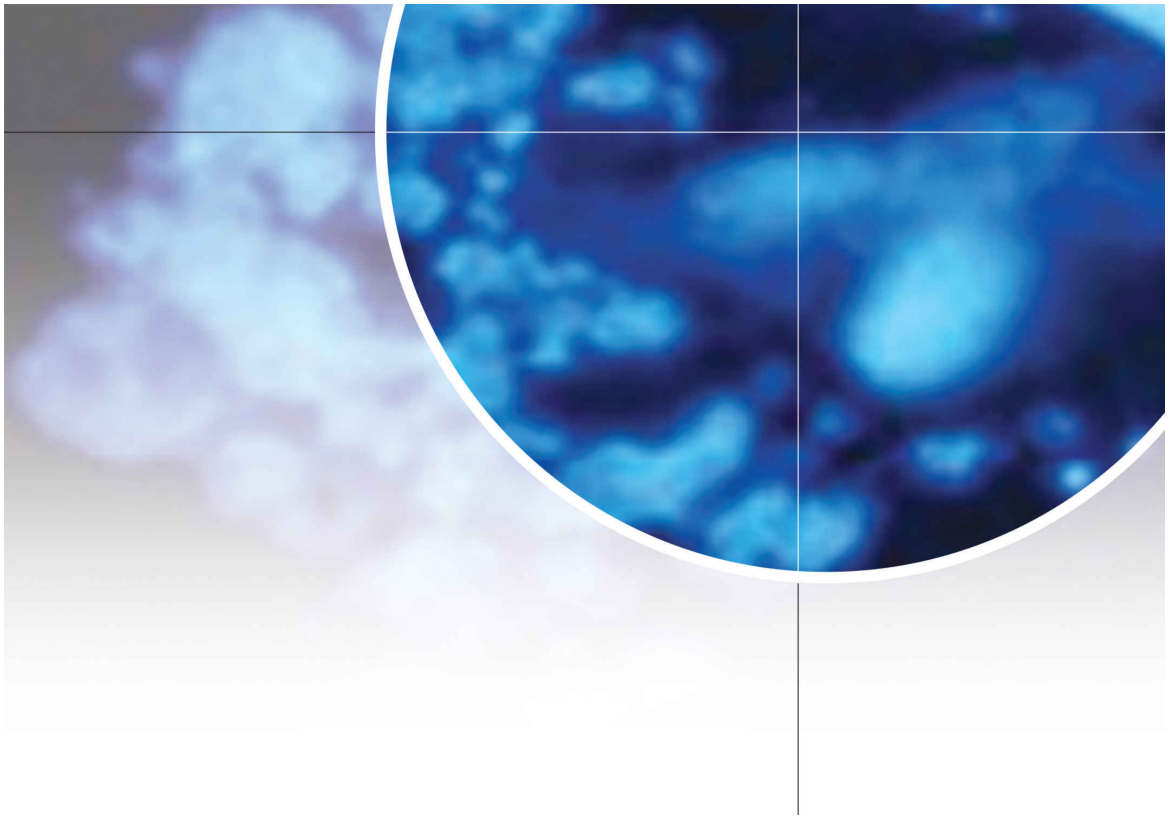
Chapter 17
The Rational Treatment of Cancer



A fluorescence microscopy image of tissue glowing blue in different sized splotches.

All substances are poisonous, there is none that is not a poison; the right dose differentiates a poison from a remedy.

Paracelsus (Auroleus Phillipus Theostratus Bombastus von Hohenheim), alchemist and physician, 1538

Doctors are men who prescribe medicines of which they know little, to cure diseases of which they know less, in human beings of whom they know nothing.

Voltaire (François-Marie Arouet), author and philosopher, 1760

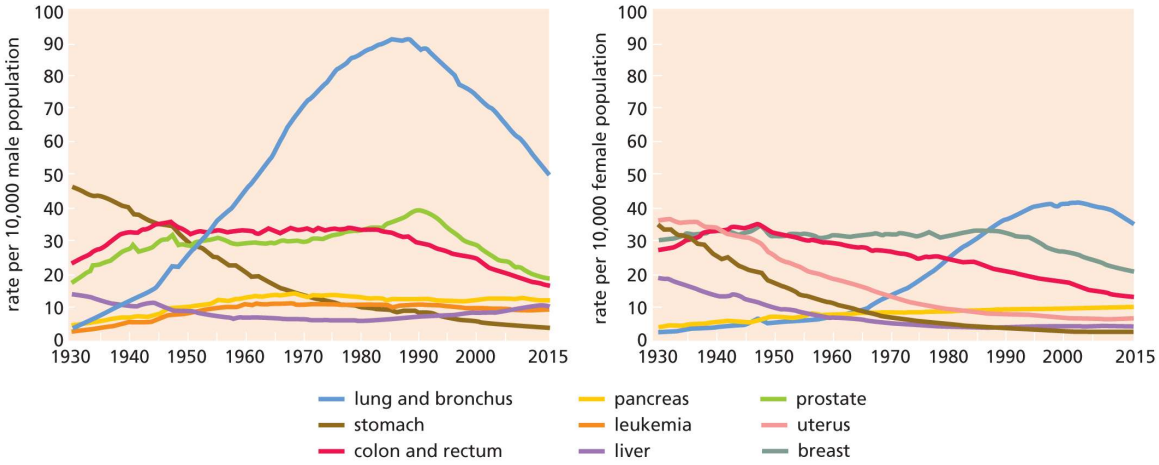
The research described throughout this book represents a revolution in our understanding of cancer pathogenesis. In 1975, there were virtually no insights into the molecular alterations within human cells that lead to the appearance of malignancies. Two generations later, we possess this knowledge in abundance. Indeed, the available information and concepts about cancer's origins can truly be said to constitute a science with a logical and coherent conceptual structure.

In spite of these extraordinary leaps forward, more limited progress has been made in exploiting these insights into etiology (that is, the causative mechanisms of disease) in order to prevent the disease and, equally important, to treat it. Most of the anti-cancer treatments in widespread use today were developed prior to 1975, at a time when the development of therapeutics was not yet informed by detailed knowledge of the genetic and biochemical mechanisms of cancer pathogenesis. Consequently, there is a widely felt frustration among molecular oncologists that the potential of their research for contributing to new anti-cancer therapeutics has not yet been realized.

The promise—still unrealized—of the new therapeutics needs to be juxtaposed with the overall progress in treating advanced tumors using the traditional strategies of surgery, chemotherapy, and radiotherapy. Significant progress in treating many tumors has been slow. For example, in 1970 in the United States, 7% of the patients diagnosed with lung cancer were still alive five years after their initial diagnosis. Five decades later, this number had risen to only 19%, a relatively minor improvement. And even this degree of therapeutic success may be illusory, because modern diagnostic techniques often detect tumors far earlier in their natural course, creating a greater time span between initial diagnosis and ultimate progression to end-stage disease.

Death rates for colon cancer have begun to fall, because of early detection and surgical removal of growths that have advanced through only the early stages of tumor progression (**Figure 17.1**; see also Figure 11.8B). However, mortality caused by the more advanced colorectal tumors has changed little—a testimonial to the failures of chemotherapy and radiation to eliminate these malignancies once they have invaded and begun to metastasize (**Supplementary Sidebar 17.1**). Moreover, age-adjusted mortality from other types of tumors has remained constant or declined relatively little. Statistics like these suggest that the potential of the traditional therapies to cure high-grade malignancies has been largely realized and that major progress in the future can only come from the novel

therapeutics whose designs are informed by our now-extensive knowledge of the molecular, biochemical, and cellular mechanisms of cancer pathogenesis.



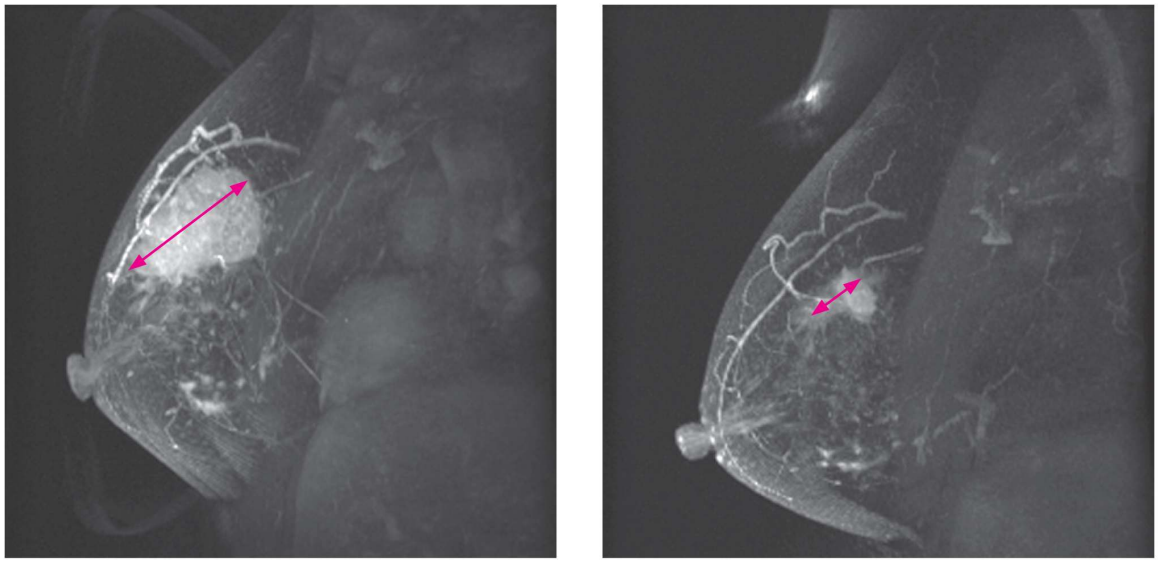
Two line graphs of the mortality rates of different cancers in males and females from 1930 to 2015. Each graph has the years 1930 to 2015 on the x axis and rate per 10,000 on the y axis. For males, pancreas, leukemia, and liver stay below 20 across all years. Stomach starts near 45 in 1930 and decreases almost to 0 by 2015. Colon, rectum, and prostate stay between 10 and 40. Lung and bronchus start near 0, peak near 90 in 1990 and then decrease to 50. For women, all cancers are below 40 and most decrease or remain constant. Liver and pancreas stay below 20. Lung and bronchus increase to a peak at 40 in the early 2000s before decreasing to 30.

Figure 17.1 Cancer mortality from 1930 to 2015: the lay of the land The statistics compiled in the United States on the age-adjusted death rates for males and females from various types of cancer reveal two different long-term trends. Mortality from several major killers has declined significantly since 1930. This resulted from changes in food storage practices and a possible reduction in *Helicobacter pylori* infection rates, in the case of stomach cancer, and to screening, in the case of colorectal cancer. The decline in mortality from lung cancer is attributable, almost entirely, to decreases in tobacco usage. However, tumors associated with the number of major sources of cancer-related death, including those associated with various forms of lung cancer, have proven resistant to most forms of traditional therapies, especially when these tumors progress to a highly malignant, metastatic stage. (Uterus includes uterine cervix and uterine corpus combined, due to limitations in COD coding prior to 1970. From American Cancer Society. Cancer Facts &

Figures, 2018. Atlanta: American Cancer Society; 2018. With permission from American Cancer Society.)

The problems confronted here are manifold. To begin, in the case of certain common cancers, we lack a good estimate of the size of the problem. How many of the cases that are diagnosed each year (yielding age-adjusted incidence) are likely to grow into life-threatening growths? And how often do treatments performed on patients with relatively benign tumors yield more morbidity than clinical benefit in terms of subsequent well-being and gains in life span?

The problem is explained by a critical lesson we learned in Chapter 11: as we grow older, small tumors appear spontaneously in a wide variety of tissues. At the same time, as diagnostic procedures become increasingly sensitive (**Figure 17.2**), we begin to detect more and more cases of cancer without a clear indication of the proportion of these that will grow into life-threatening tumors. This problem is immense, given the limited ability of oncology clinics and funds to respond to an ever-increasing number of cases (**Sidebar 17.1**).



Two M R I images of breast tissue before and after chemotherapy. In both images there is a white mass in the breast tissue. In the pre-chemotherapy image, the longest dimension of the mass is 47 millimeters. In the post-chemotherapy image, the longest dimension of the mass is 16 millimeters.

Figure 17.2 High-resolution noninvasive imaging of human tissues The development of magnetic resonance imaging (MRI) has enabled increasingly higher-resolution noninvasive visualization of living tissues. MRI now allows breast tumors of very small size (several millimeters in diameter) to be detected and, as shown here, makes it possible to view the progress of anti-tumor therapy—in this case chemotherapy with an anthracycline cytotoxic agent—in exquisite detail. Widespread use of such highly sensitive imaging techniques has resulted in increases in the registered incidence rate of breast cancer (resulting from detection of disease that would previously have eluded detection) with unclear effects on the ultimate mortality of the disease. (Courtesy of N.M. Hylton and L.J. Esserman.)

Sidebar 17.1 How common are cancers that require clinical intervention?

The development and use of diagnostic procedures of ever-increasing sensitivity led to steep increases in the incidence of breast and prostate cancers during the second half of the twentieth century. In the case of the breast, the incidence of carcinomas increased progressively during the late twentieth century and then leveled off (see Figure 17.3). Some of these growths will eventually become life-threatening and many others will not. However, incidence rates are an artifact of technology, and as diagnosis improves (see Figure 17.2), the age-adjusted incidence will increase in lockstep unless the images generated by these new diagnostic techniques are interpreted with caution. Hence, the only truly rigorous and solid measurements are those associated with mortality.

A recent study of breast cancer performed post mortem on women who died of a variety of causes estimated that at the age of 80, at least two-thirds of women carry breast carcinomas (whereas only ~4% will die from breast cancer). An even larger number (~80%) applies to post mortem studies of prostate carcinomas in men of this age. Thus, if the diagnostic procedures performed on living patients were as sensitive as those implemented upon autopsy, the estimated incidence of breast and prostate carcinomas would increase dramatically, because even more non-life-threatening cancers would be registered (see also **Supplementary Sidebar 17.2**).

As discussed in the next section, our rapidly evolving understanding of disease pathogenesis may soon allow us to judge more accurately how many cancers are deserving of aggressive treatment and how many can be safely left untreated. At

the same time, our improving insights into specific disease processes, such as the development of metastases, have revealed how traditional, widely used forms of therapy have not served many cancer patients well (**Supplementary Sidebar 17.2**).

In most of this chapter, we explore therapeutic strategies under development or recently introduced into the clinic and examine how their development has been informed by what we have learned in the earlier chapters of this book. The goal here is not to survey the full range of current research in these areas. That would be unreachable: a 2018 compilation of anti-cancer therapies in pre-clinical development or in clinical testing listed more than 1100 potential therapeutic agents that were being pursued by pharmaceutical companies and biotechnology firms. The agents under development included low–molecular-weight drugs, proteins, antibodies and antibody conjugates, and gene therapy strategies, including viral vectors.

Rather than being encyclopedic, we will concentrate here on a small number of recently developed therapies that illustrate how discoveries described in the previous chapters have inspired novel strategies for treating cancer and how molecular diagnosis will increasingly play a part in the development and clinical introduction of novel therapies. These therapeutic strategies hold great promise, and invariably their true potential is yet to be realized. The anecdotes surrounding the development of each of these agents are interesting and provocative because they teach important lessons about the triumphs and pitfalls of developing novel anti-cancer treatments. Note that the recent development of immunotherapies has profoundly influenced both the current treatment of multiple cancer types and the future prospects for the treatment of malignancies that have traditionally been refractory to therapy. These dramatic developments have been described in some detail in Chapter 16.

Almost all the research findings described throughout this textbook will stand the test of time and be considered credible and correct (though perhaps not that interesting) a generation from now. However, those who love certainty and eternal truths will find the stories that follow below to be unsatisfying for a very simple reason: the work reported is in great flux and many outcomes are uncertain. Many of the newer therapies will seem quaint and anachronistic a decade after this chapter is written. The campaign to convert insights about cancer’s molecular causes into new ways of curing disease has just begun.

Note also that we will pass over descriptions of how molecular biology is changing cancer *prevention* strategies. Thus, in this chapter we will not examine the major advances that have been made in developing vaccines that protect against hepatitis B virus (HBV) and human papillomavirus (HPV) infections (for example, see Supplementary Sidebar 15.5); these vaccines should be highly effective in reducing the incidence of hepatomas and cervical carcinomas, which are major sources of cancer-associated mortality in certain parts of the world. (If past public health measures are any guide, the prevention of cancer, that is, the reduction of disease *incidence*, will ultimately yield far greater reductions in overall disease-related *mortality* than will therapies of the sort discussed in this chapter.)

Simple logic would dictate that the newer, "rationally designed" agents, because they attack specific, identifiable molecular targets, are likely to be far more effective in eradicating tumors and less encumbered with toxic side effects than are older agents; the latter were discovered through empirical trial-and-error testing that was undertaken without any foreknowledge of the biochemistry and molecular biology of cancer cells. However, as we will see in Section 17.2, the more traditional ways of treating neoplastic disease have proven to be highly effective in halting disease progression and reducing cancer-associated mortality, explaining why these treatments continue to merit our attention. Such curative outcomes are, ironically, still not the endpoints achieved by most of the recently developed therapies, as we will see.

OceanofPDF.com

17.1 The development and clinical use of effective therapies will depend on accurate diagnosis of disease

In previous chapters, we repeatedly categorized cancers in terms of their tissues of origin and their stages of clinical progression. Almost always, these assignments have been dictated by the appearance of normal and malignant tissues under the microscope. On many occasions, to be sure, we have refined these classifications by describing certain molecular markers [for example, expression of HER2 in breast cancers and the implications that they hold for prognosis (see Figure 4.3A)], but in general, histopathology has reigned supreme in our discussions, as it has in the practice of clinical oncology for almost a century.

It has become increasingly clear, however, that the traditional ways of classifying cancers have limited utility. Truly useful diagnoses must inform the clinician about the underlying nature of diseases and, more important, how each disease entity will respond to various types of therapy. As we have learned more about human cancers, we have come to realize that many human cancers that have traditionally been lumped together as examples of a single disease entity should, in fact, be separated into several distinct subcategories of a disease. This tendency to view cancer as a uniform entity helps to explain why many existing anti-cancer therapeutic strategies used over the past three decades have had such low overall success rates, in that they have treated tumors of a certain class as representatives of a homogeneous disease rather than of multiple distinct subtypes of disease, some of which might be responsive to targeted therapeutic attack, whereas others might be quite resistant. These response rates also have important implications for the development of new drugs (**Supplementary Sidebar 17.3**).

Stated differently, the clinical oncologist really confronts two issues: Should a diagnosed tumor be treated, and if so, what available therapies are appropriate for the subtype of tumor that has been identified? In an ideal world, the decision to proceed with treatment should be a challenging one requiring detailed knowledge of the idiosyncrasies of the diagnosed tumor, but in the real world, it is often simplified: treat almost all tumors (with the exception of skin cancers) aggressively in order to reduce as much as possible the likelihood of eventual life-threatening clinical progression.

Ideally, the complexity of the decision to proceed with treatment should take into account that diagnosed tumors fall into three classes:

1. Indolent tumors that have low invasive and metastatic potential and will remain in such a state during the lifetime of the patient.
2. Highly aggressive tumors with a propensity to metastasize that have, with high probability, disseminated by the time that the primary tumor has been diagnosed.
3. Tumors of intermediate grade that have the potential to disseminate but can be excised or treated with cytotoxic therapies before dissemination occurs and life-threatening metastases are formed.

Tumors of the first class are generally not worthy of treatment, including surgery, and should be left undisturbed. (Indeed, surgery may, under certain conditions, provoke otherwise-indolent growths to become clinically apparent if not aggressive.) One illustrative example of these is pancreatic neuroendocrine tumors (NETs)—that is, tumors of the pancreatic islets (see Figure 13.36)—which constitute about 3% of pancreatic carcinomas and are discovered incidentally during high-resolution imaging, often undertaken for other conditions. Asymptomatic patients with these low-grade "incidentalomas," as the tumors are termed amusingly by oncologists, confront a 90% five-year progression-free survival. Like any type of pancreatic surgery, excision of these tumors is accompanied by a high degree of post-surgical morbidity; such morbidity may eclipse the clinical benefit that these patients receive from surgery, given the low likelihood of clinical progression. [Contrast their prognosis with that of a recently diagnosed pancreatic exocrine adenocarcinoma patient (see **Supplementary Sidebar 11.5**), whose overall five-year survival is only ~5%.] At present, diagnostic criteria do not distinguish between the small subset of NETs that will eventually progress and the great majority that are unlikely to progress during a patient's lifetime. Papillary thyroid carcinomas represent another class of incidentalomas: in one of the few systematic post mortem studies of this disease, a Finnish research group found these growths in one-third of those autopsied, whereas only 0.07% of annual deaths (in the United States) can be attributed to this disease.

Truly effective treatments for most kinds of metastases are not available at present, raising the question whether tumors of the second class are worth treating, as they will become lethal no matter what therapies are attempted. (The proviso here is that existing treatments may ameliorate symptoms over an extended period of time and may even forestall the inevitable, thereby extending patients' symptom-free life spans significantly.) Cynics argue simplistically that patients carrying these two classes of tumor should be left untreated, because the long-term outcome is predictable no matter what clinical strategy is chosen. Unappreciated by the cynics is the possibility that the sub-optimal responses of the second class of tumors to existing therapies will serve as foundations for the development in the future of vastly more effective therapies that will save those who, at present, confront inevitable disease progression and death.

The third class of tumors—those of intermediate grade—are those that should and will command most of our attention in this chapter—the “in-between” tumors whose treatment will actually prevent metastatic progression and achieve long-term, even curative responses. In reality, in countries like the United States where concerns about neglectful treatment verging on medical malpractice dominate, tumors of all classes are treated, often aggressively. Such unfocused treatments will soon become issues of the past, if only because the costs of unnecessary therapies will no longer be economically sustainable.

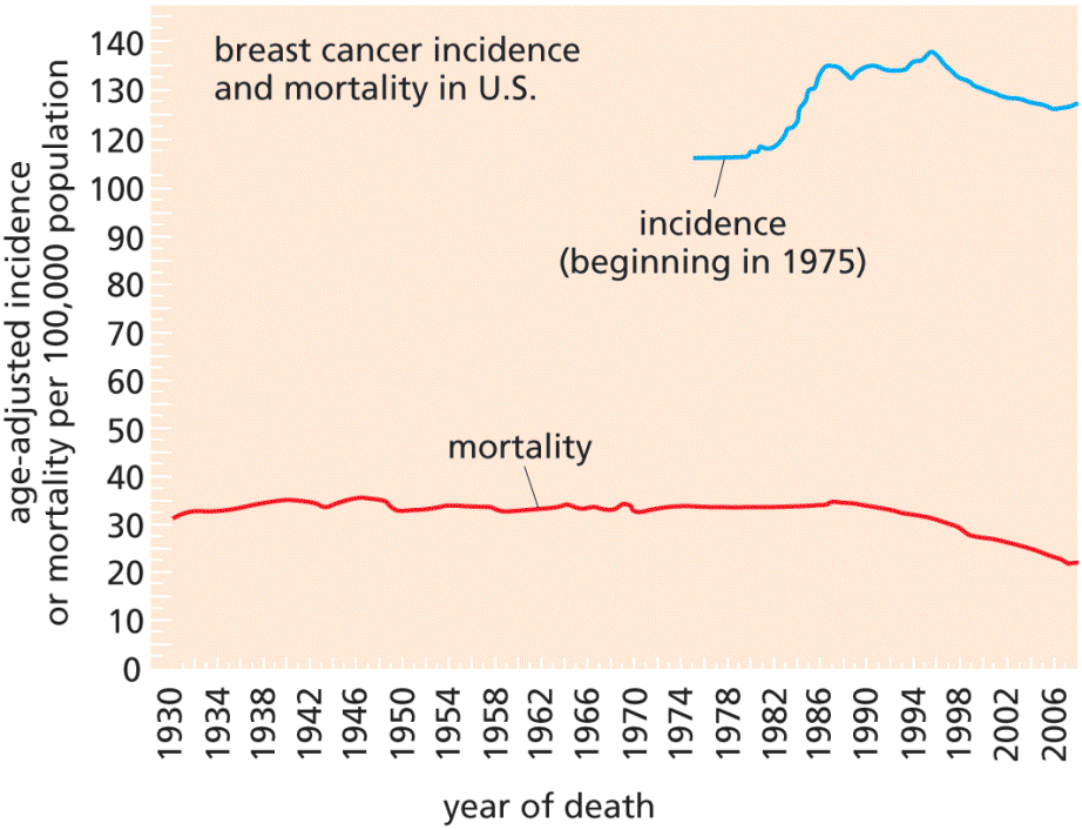
At present, such uniformly applied therapies may have other downsides beyond economic costs. Indeed, anti-cancer treatments often cause numerous side effects and some may actually increase the incidence of second-site cancers arising years later. For example, in the early 1980s, breast cancer patients receiving the then-standard dose of cyclophosphamide (a chemotherapeutic drug that is also an alkylating agent; **Table 17.1**) experienced a 5.7-fold increased risk of subsequently developing acute myelogenous leukemia (AML), ostensibly the consequence of the mutagenic actions of this drug. (Many current treatment protocols use lower drug dosages and result in greatly decreased incidence of such second-site cancers.) All this points to the great need for more refined diagnostic tools—ones that can accurately predict responsiveness to various anti-tumor therapies and allow the oncologist to avoid use of therapies when they are not needed because they are highly unlikely to succeed.

Table 17.1 Examples of alkylating agents or other DNA-modifying agents used to treat cancer

Name	**Chemical structure**	**Effects on DNA**	**Examples of clinical use**
bleomycin	nonribosomally synthesized oligopeptide	strand breaks	Hodgkin’s lymphoma, squamous cell carcinoma
cyclophosphamide	nitrogen mustard analog	cross-links N^7 of guanine	lymphoma, leukemia
dacarbazine	nitrogen mustard analog	methylation of guanine	Hodgkin’s lymphoma, melanoma

Name	Chemical structure	Effects on DNA	Examples of clinical use
melphalan	nitrogen mustard analog	alkylates N^7 of guanine	multiple myeloma
chlorambucil	nitrogen mustard analog	base alkylation, cross-links	chronic lymphocytic leukemia
carboplatin/cisplatin	alkylating-like agent	intra-strand cross-links	breast, ovarian, testicular cancer
temozolomide	alkylating agent	methylation of guanine	glioblastoma multiforme

We can focus for the moment on female breast cancers in the United States to provide an illustrative example. In 2018, about 266,000 cases of invasive breast cancer were diagnosed together with 64,000 noninvasive (*in situ*) forms of the disease. That year, about 41,000 women were predicted to die from the disease. Most patients with invasive mammary carcinomas were treated with aggressive chemotherapy. The age-adjusted death rate from breast cancer in the United States did not change significantly throughout most of the twentieth century (**Figure 17.3**) during a period when truly effective therapies were not available, suggesting that a comparable annual frequency of life-threatening breast cancers continues to be formed today and that many of the vastly larger numbers of invasive breast carcinomas currently being diagnosed are not likely to cause death, even without therapeutic intervention, much like the prostate cancers that are diagnosed in vast numbers in the West (**Supplementary Sidebar 17.4**). As screening for breast cancer increases and the power to detect small, previously overlooked tumors improves (see Figure 17.2), this disparity between breast cancer incidence and mortality is likely to grow.



A line graph of breast cancer incidence and mortality in the United States. On the x axis is year of death from 1930 to 2006. On the y axis is age-adjusted incidence or mortality per 100,000 population from 0 to 140. Mortality stays relatively constant between 30 and 40 until 1990 when it starts to decrease. By 2004, it is around 20. Incidence rates start in 1975 near 120. They sharply increase to between 130 and 140 between 1986 and 1996 before dropping to 125.

Figure 17.3 Breast cancer incidence vs. mortality in the United States The age-adjusted incidence of breast cancer has been increasing steadily over the past several decades, whereas mortality from this disease was quite constant until the end of the twentieth century, when it began to decline significantly. Most of the increase in incidence appears to be attributable to increased screening, but a small proportion of it may have resulted from real changes in the rate at which the disease strikes because of changes in reproductive practices, nutrition, obesity, age of menarche and menopause, and so forth. (From A. Jemal et al., *CA Cancer J. Clin*. 55:10–30, 2005. With permission from John Wiley & Sons.)

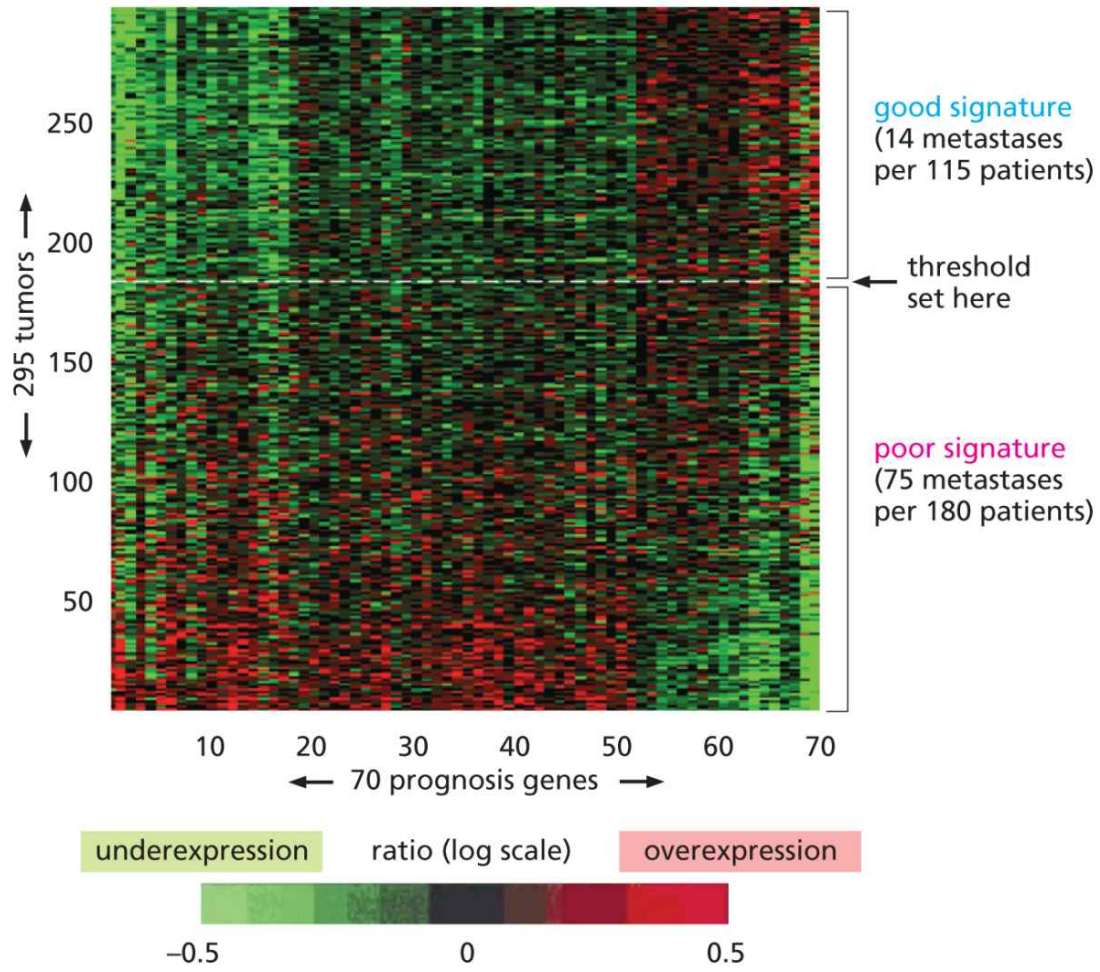
Statistics like these underscore the desperate need to develop molecular markers that enable oncologists to distinguish between those tumors that truly require aggressive treatment and those that can be monitored repeatedly for signs of progression (the

practice termed “watchful waiting”). In the case of other types of cancer, equally important distinctions must also be made, but of a far grimmer sort—between those cancers that are likely to show some significant response to therapy and those that will not, in which case compassionate care dictates that the disease should be allowed to run its natural course.

Gene expression analysis, of the type first described in Figure 13.20, has provided clinicians with an additional approach to stratify cancers—to classify them into subgroups having distinct biological properties and prognoses. RNAseq, a key analytical tool of the science of functional genomics, allows a researcher to survey the expression levels of a set of genes (often involving virtually all genes in the genome whose expression can be measured in a tissue preparation). Subsequent computerized analyses of these expression data using bioinformatics make it possible to identify patterns of gene expression characteristic of specific tumor types and subtypes. Additionally, these analyses can reveal small subsets of the genes whose expression (at characteristically high or low levels) correlates with a specific biological phenotype, drug responsiveness, or prognosis. For example, the expression of a cohort of several dozen genes by a tumor may suffice to serve, on its own, as a strong predictor of its degree of progression or its association with one or another specific subtype of cancer.

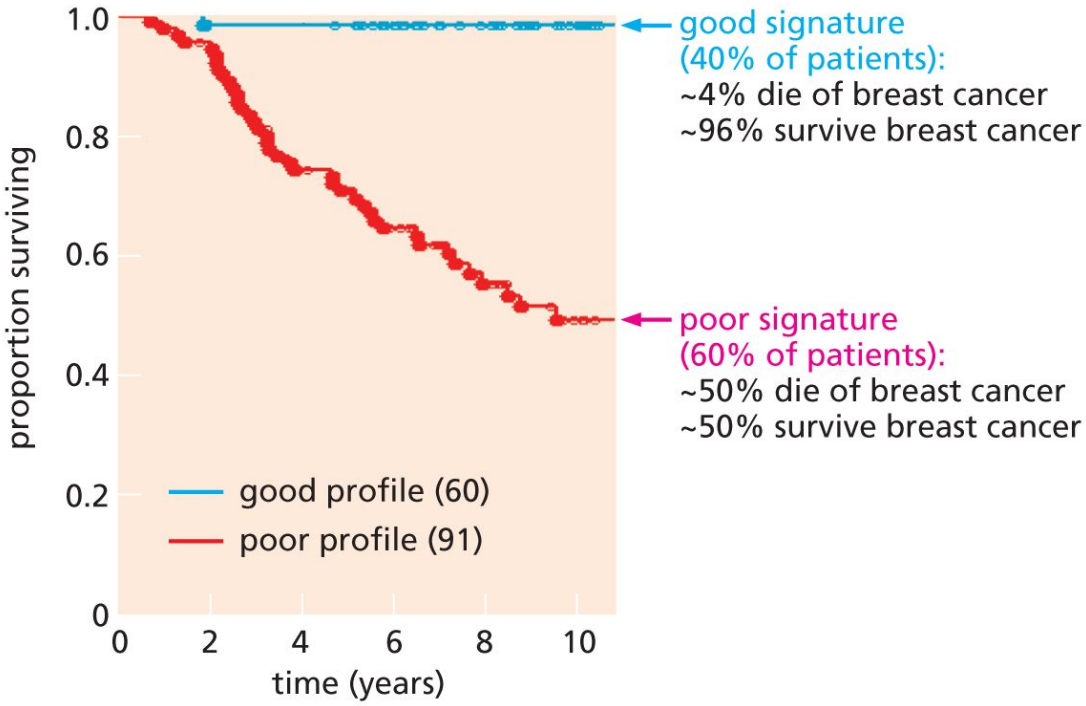
In the case of breast cancers, there has been a crying need to distinguish those primary tumors that are likely to become metastatic from those that will remain indolent and are therefore not likely to spread during the lifetime of the patient. Traditionally, the main prognostic parameters that have been used to predict the course of breast cancer development have been patient age, tumor size, number of involved axillary lymph nodes, histological type of the tumor, pathological grade, cell proliferation rate, and receptor status (that is, the expression of the estrogen, progesterone, and HER2 receptors). Because these factors, when used singly or in combination, do not yield prognoses with a high degree of accuracy, most patients diagnosed with primary invasive breast cancers in the United States have been treated aggressively, even though only ~19% of such patients will ever develop life-threatening disease.

The combined use of gene expression analysis and bioinformatics has made it possible to predict the clinical course of breast cancer progression with more than 90% accuracy (**Figure 17.4**). Such a high prognostic accuracy holds the promise of sparing many women exposure to unnecessary chemotherapy; in these women, gauged statistically, the risks incurred by the therapy may actually exceed the risk of life-threatening cancer development. And in the future, the details of gene expression analyses are likely to inform the oncologist about the treatment protocol that is most likely to yield a durable clinical response or even a cure (**Sidebar 17.2**).



An expression array shows how underexpression and overexpression of 70 genes is correlated to the occurrence of tumors. A threshold is set in the middle. A good signature means there were 14 metastases per 115 patients. A poor signature means there were 75 metastases per 180 patients. For some genes, an underexpression was the good signature, and overexpression was the poor signature. For others, it was the opposite.

(A)



A graph with time in years from 0 to 10 on the x axis, and proportion surviving on the y axis. 40 percent of patients had a good signature. Of these, by year 10, 4 percent die of breast cancer and 96 percent survive breast cancer. 60 percent of patients had a poor signature. Of these, by year 10, 50 percent die of breast cancer and 50 percent survive breast cancer.

(B)

Figure 17.4 Stratifying breast cancers using functional genomics (A) Expression arrays were used to analyze the gene expression of 295 primary breast cancers diagnosed in women under 53 years old. The group included patients with metastatic cells in the axillary lymph nodes draining the mammary glands as well as patients whose lymph nodes were free of cancer cells. Bioinformatics analyses of these tumors were then employed to choose a set of 70 “prognosis genes” whose expression could be used to stratify these breast cancer patients (arrayed along vertical axis), whose clinical course had been followed for a mean time of 7 years. The expression levels of these 70 genes (arrayed along horizontal axis, names not given) together with information about the patients’ clinical history was then used to set a threshold that separated tumors that had a “good expression signature” from tumors that had a “poor expression signature.” (B) This Kaplan–Meier plot reveals the stratification of a group of 151 breast cancer patients whose survival had been followed for 10 years following initial diagnosis. Using the criteria of panel A, they could be separated into two groups with dramatically different clinical courses. Taken together with other factors (such as the efficacy of

chemotherapy), calculations indicate that women whose tumors carry a good expression signature derive virtually no benefit from adjuvant chemotherapy. (From M.J. van de Vijver et al., *N. Engl. J. Med*. 347:1999–2009, 2002. With permission from Massachusetts Medical Society.)

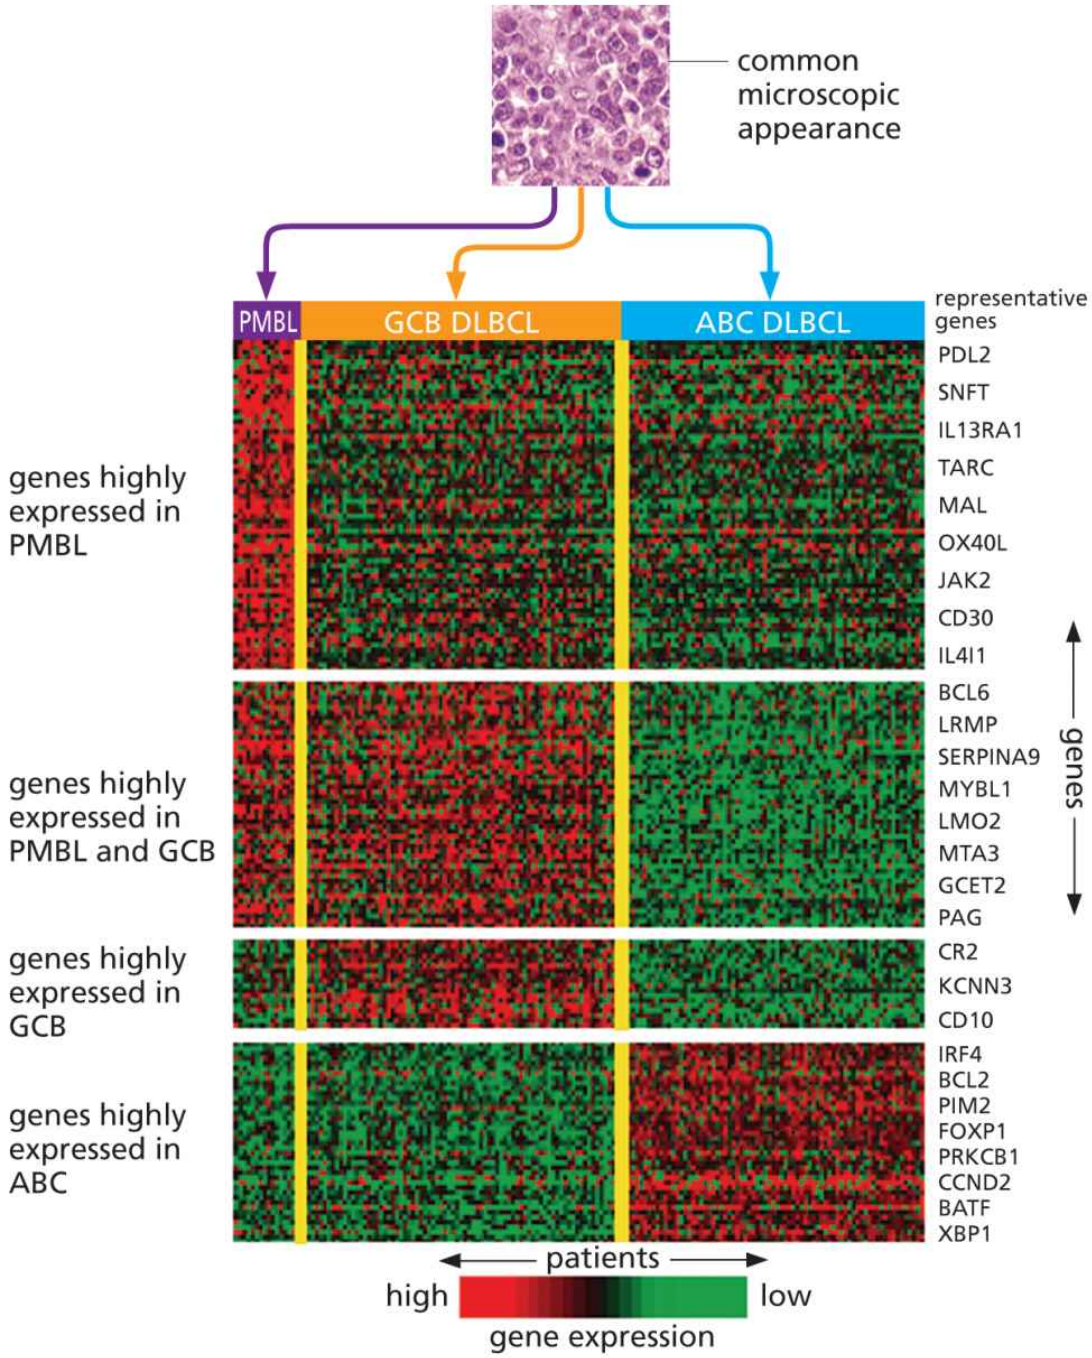
Sidebar 17.2 RNA expression and tumor origins

As we read earlier in Chapter 11, the somatic mutations and epigenetic alterations that tumors sustain en route to full-blown malignancy rarely eradicate the influence of the differentiation programs of their normal cells-of-origin (see Sidebar 11.2 and Figures 11.13 and 14.50). In most tumors, these programs are transmitted heritably from one cell generation to another, in spite of the profoundly disruptive effects of various mutations and heritable epigenetic alterations acquired during the course of tumor progression. These differentiation programs work hand in hand with the somatic mutations and epigenetic alterations to dictate cancer cell phenotype and thus responsiveness of a tumor to therapies.

These complex interactions between genetic and nongenetic determinants of cancer cell behavior cannot be discerned by sequencing tumor cell genomes, creating a need to systematically monitor the nongenetic determinants of cancer cell behavior. In principle, cell phenotype could be surveyed in a systematic and quantitative way through proteomic analyses that reveal the complex array of proteins expressed by cancer cells, the levels of these proteins, and their states of post-translational modification. At present this is challenging at the single cell level, indicating the need to use gene expression analyses as the practical alternative for surveying cancer cell phenotype. In the future, complex bioinformatic algorithms will need to be developed to integrate the results of gene expression analyses with those of tumor genome sequencing in order to produce a more complete picture of the molecular and biochemical state of diverse sets of cancer cells within a tumor that should prove even more useful than the results currently achieved by RNAseq and scRNAseq analyses alone.

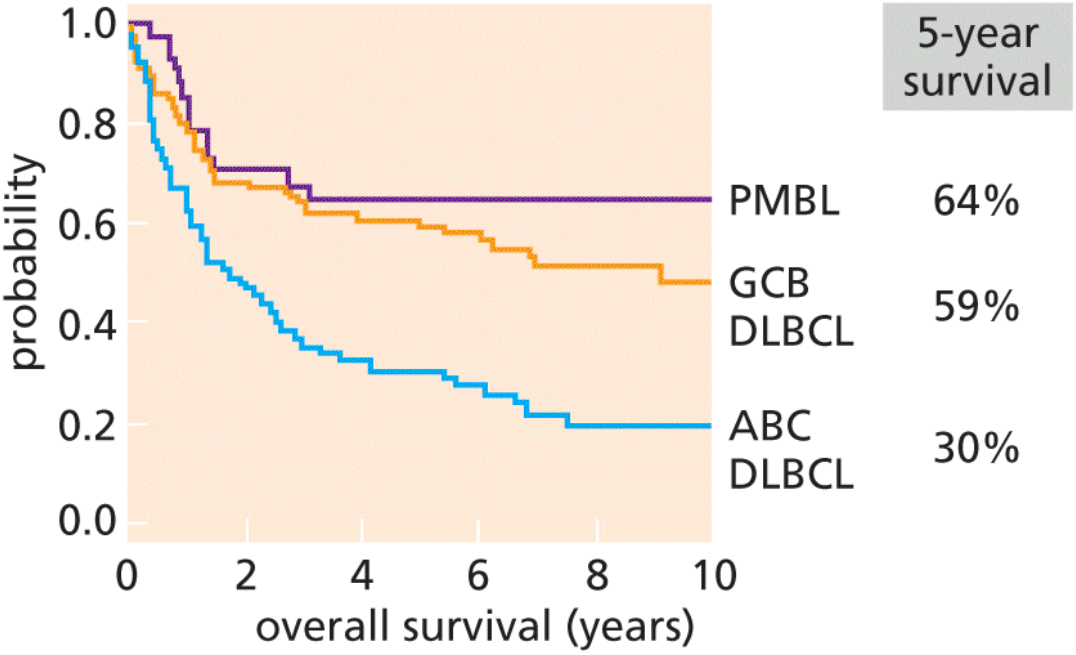
Analyses of this sort are only the beginning steps in a large-scale effort to examine a variety of human cancer types by means of gene expression. The resulting information should make it possible to stratify the cancer types into subtypes and, based on the resulting information, to devise therapies tailored to each specific subtype. As an illustrative example, diffuse large B-cell lymphomas (DLBCLs) have presented a quandary to the oncologist because their outcomes are so variable in the clinic, with some patients dying soon after diagnosis and many others being cured, or at least achieving 10-year remissions without any clinical symptoms. At the same time, all these tumors have a very similar appearance under the microscope (**Figure 17.5A**).

Through the use of gene expression analysis in combination with additional high-resolution approaches, we now know that this malignancy is actually composed of several distinct molecular disease subtypes, seemingly originating from cells that have passed through different stages of B-cell differentiation (Figure 17.5A). These subtypes, which include germinal-center B-cell-like (GCB) lymphomas, activated B-cell-like (ABC) lymphomas, and primary mediastinal B-cell lymphomas (PMBL; Figure 17.5B), show distinct clinical outcomes following standard chemotherapy.



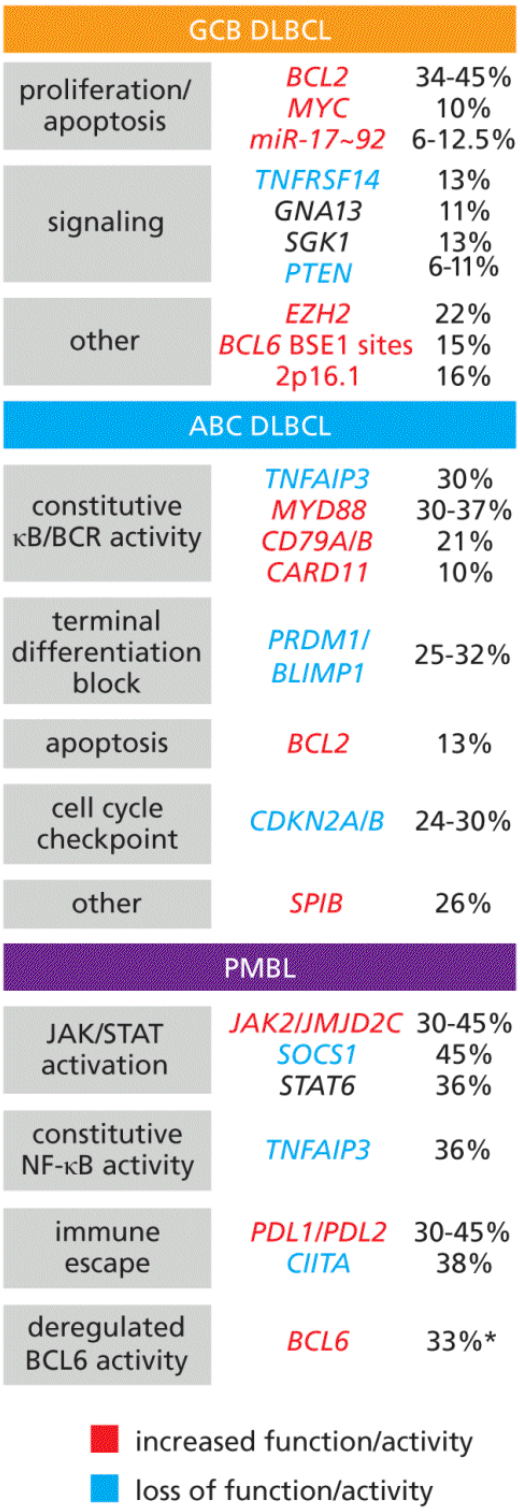
A microscopy image shows that cells from three subtypes of B cell neoplasia are all stained purple. A gene expression analysis below lists 28 different representative genes along with their gene expression levels. Some genes are only highly expressed in subtype P M B L. Some genes are highly expressed in subtypes P M B L and G C P. Some genes are only highly expressed in subtype G C B. Some genes are only highly expressed in subtype A B C.

(A)



A graph shows the 5 year survival and overall survival for three subtypes of B cell lymphomas. On the x axis is years and on the y axis is the survival probability. The 5 year survival of A B C D L B C L is 30 percent and the 10 year survival is 20 percent. The five year survival of G C B D L B C L is 59 percent and the 10 year survival is 50 percent. The five and ten year survival of P M B L is 64 percent.

(B)



A table shows characteristics of different tumor subtypes. In the G C B D L B C L subtype, there is enhanced expression of genes that cause proliferation, apoptosis, and other effects, and loss of genes that lead to signalling. In the A B C D L B C L subtype there is enhanced expression of genes that lead to

constitutive kappa B slash B C R activity, apoptosis, and other effects. There is loss of genes that lead to terminal differentiation block, cell cycle checkpoint, and constitutive kappa B slash B C R activity. In the P M B L subtype, there is enhanced expression of genes that lead to JAK slash STAT activation, immune escape, and deregulated B C L 6 activity. There is loss of genes that lead to JAK slash STAT activation, constitutive N F kappa B activity, and immune escape. The percentage present of these alterations ranges from 6 to 45 percent.
(C)

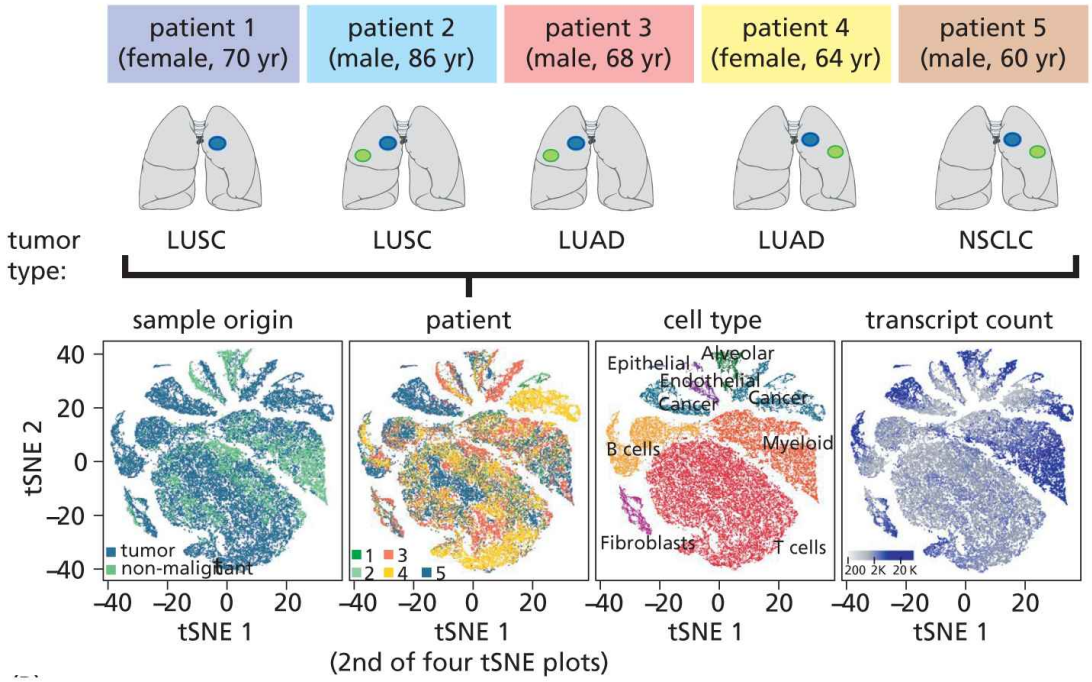
Figure 17.5 Stratification of diffuse large B-cell lymphomas (A) DLBCLs represent a group of several subtypes of B-cell neoplasia that are essentially indistinguishable in the microscope from one another and from the microscopic appearance of primary mediastinal B-cell lymphomas (*above*). However, use of gene expression analysis (*below*) allows these tumors to be stratified into three subtypes, termed primary mediastinal B-cell lymphomas (PMBLs), germinal-center B-cell (GCB) DLBCLs, and activated B-cell-like (ABC) DLBCLs. In this expression array, a set of genes whose expression levels have been found to be useful in making this stratification is plotted along the vertical axis, and a set of patient tumors (*unlabeled*) is plotted along the horizontal axis. (B) This Kaplan–Meier curve illustrates the greatly differing disease courses that patients with the three subtypes experience. (C) The tumors that are classified through the expression analyses shown in panel A exhibit distinct genetic alterations (shown as present in the indicated percentage of each tumor subtype), including mutations resulting in a loss of gene function (*blue*) and mutations and chromosome translocations resulting in enhanced gene activity or expression (*red*). (A, top, from M. Roschewski, L.M. Stuadt, and W.H. Wilson, *Nat. Rev. Clin. Oncol*. 11:12-13, 2014. With permission from Nature. Bottom, from L.M. Staudt and S. Dave, *Adv. Immunol*. 87:163–208, 2005. With permission from Elsevier. B, from A. Rosenwald et al., *J. Exp. Med*. 198:851–862, 2003. With permission from Rockefeller University Press. C, from L. Pasqualucci and R. Dalla-Favera, *Cancer Cell* 25:132, 2014. With permission from Elsevier.)

The combination of next-generation DNA sequencing with expression-based classification has further defined a molecular architecture of these lymphoma subtypes. Of these three subtypes, both the activated ABC lymphomas and the PMBLs exhibit genetic and epigenetic alterations that lead to high levels of NF-κB activity (see Figure 6.22A and 17.5C); this transcription factor (see Section 6.12) appears to be driving their proliferation and protecting them from apoptosis. In ABC lymphomas, NF-κB activity can by driven by constitutive B-cell receptor signaling or mutations, like those present in Myd88 or TNFAIP3, which promote or inhibit repression of NF-κB induction. In contrast, GCB tumors depend upon a distinct set of anti-apoptotic

signals, including the overexpression or constitutive activation of Bcl2 or Bcl6 (see Section 9.13), or mutations in epigenetic regulators, such as EZH2, that maintain the germinal center cell state, that is, the phenotypic state characteristic of cells in the lymphoid organs in which B cells mature.

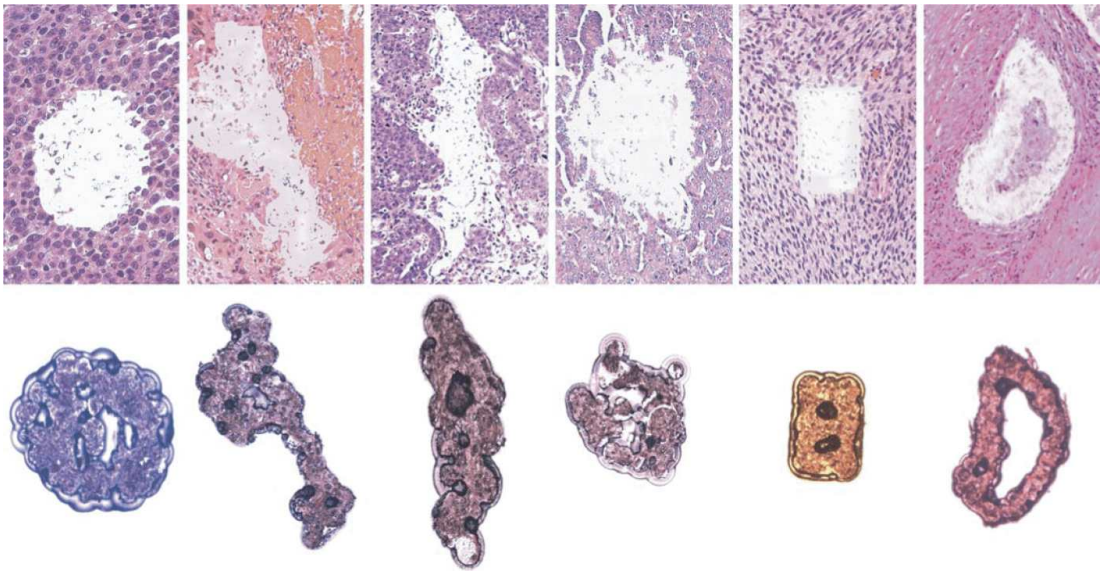
The identification of deregulated signaling and driver mutations in lymphoma subtypes has prompted clinical efforts to target these particular pathways in primary tumors and in those resistant to chemotherapy. To summarize, expression analysis of tumor-derived RNA can provide a molecular pathological characterization (rather than a microscope-based histopathological characterization) of a tumor that can then be combined with DNA sequencing analysis to identify molecular targets within these cancer cells that might be targeted by appropriate pharmacological agents. It remains to be seen whether the identification of these vulnerabilities of distinct lymphoma subtypes will result in new first-line treatments for most lymphoma patients.

Interpretation of the gene expression patterns of tumors of complex histology, such as carcinomas composed of epithelial, endothelial, immune, and other stromal cell types, is often confounded because the RNA transcripts being measured represent mixtures deriving from multiple cell types rather than the transcripts produced by the neoplastic cells in these tumors. This problem may be addressed by bioinformatic analyses that are able to deconvolute the contributions of the various distinct cell types in a tumor being analyzed. More precise assessments can be made through use of recent advances in RNA sequencing (**Figure 17.6A**). Specifically, the quantification of multiple transcripts produced by individual cells—both normal and neoplastic—can now be performed. This experimental procedure, termed single-cell RNA sequencing or scRNAseq, involves isolating single cells and generating amplified cDNA libraries representing the transcripts of each of these cells, which can then be sequenced using conventional DNA sequencing procedures (**Sidebar 17.3**).



A diagram shows five patients along with their lung tumor type. Patient 1 is a 70 year old female with an L U S C tumor. Patient 2 is an 86 year old male with an L U S C tumor. Patient 3 is a 68 year old male with an L U A D tumor. Patient 4 is a 64 year old female with an L U A D tumor. Patient 5 is a 60 year old male with an N S C L C tumor. Below these are four t S N S plots. One is of the sample origin, one is of the patient, one shows cell type, and one shows transcript count. They all are of the same lung section and have t S N E 1 on the x axis and t S N E 2 on the y axis.

(A)



Six histology images of tissue with tumors removed. A 3 D model of the tumor is shown below the histology image. The empty space in the tissue matches the shape of the tumor below.

(B)

Figure 17.6 scRNAseq and laser-capture microdissection of tumors High-resolution techniques are increasingly used to examine the cellular pathology of human cancer. (A) Lung tumors excised during surgery are disassociated into single cells and analyzed for mRNA content. The transcriptome of each cell can then be used to demarcate which cells are neoplastic cells vs. those deriving from adjacent nonmalignant tissue, which specific stromal cell types are present within individual tumors, and how the representations of tumor and stromal cell types vary within individual tumors and between patients. The individual cells with similar transcriptomes can be grouped together using a statistical algorithm that displays them in a two-dimensional tSNE plot, examples of which are presented here. The combined expression data provides a new kind of tumor pathological analysis that extends beyond that afforded by more established cell staining and immunohistochemical approaches. (B) Laser-capture microdissection (LCM) of tumor sections allows for the precise isolation of small sets of tumor cells within a topologically defined area of a tumor. Here each removed patch of tumor cells (*right*) is aligned with the remainder of the tumor section that is left behind following this removal (*left*). This approach can be combined with scRNAseq to determine the gene expression states and the level of heterogeneity that exists between cells in distinct areas of the same tumor. (A, from D. Lambrechts et al., *Nat. Med.* 24:1277–1289, 2018. With permission from Nature. B, Reprinted with permission of Springer Nature: Humana Press, Testicular Germ Cell Tumors,

Sidebar 17.3 Examining gene expression in tumors at the single-cell level

scRNAseq technology now enables a deep exploration of the range of distinct cell types within a given tumor. For example, the mRNA species produced by individual stromal cells, as revealed by scRNAseq, can be used to determine the inflammatory or immune characteristics of the tumor-associated stroma. It can also be used to identify characteristics of infiltrating stromal cells that may modulate tumor behavior or therapeutic response. Moreover, this technology has been used to characterize intra-tumoral heterogeneity among neoplastic cells themselves, that is, the phenotypically diverse subpopulations of neoplastic cells that arise in advanced tumors (see Section 11.6). Among other benefits, scRNAseq can identify subsets of cancer cells that are refractory to treatment and would not be recognizable by bulk RNA expression analysis (that is, sequencing the transcripts produced by unfractionated mixtures of cells; see Figure 17.6A).

An extension of scRNAseq that will be employed increasingly in the future is its combination with the technique of laser-capture microdissection (LCM; see Figure 17.6B) in order to characterize the transcriptomes of physically isolated cells or groups of cells prepared from microscopic sections. Such combination analyses will reveal the precise intra-tumoral location and the RNA expression states of a diverse set of normal and tumor cells. In the future, such analyses will provide a high-resolution diagram of the functional interactions between the spatially associated cell types within a tumor. This information will help, in turn, to define mechanisms by which the tumor microenvironment promotes phenotypic heterogeneity among tumor cells or supports processes like tumor cell metastasis, immune protection, or therapeutic resistance.

In addition to these various analyses of cell transcripts, technical advancements in DNA sequencing have enabled genome-scale analyses to be performed at an increasingly accessible cost. Thus, next-generation DNA sequencing has become an increasingly common cancer diagnostic tool. Targeted mutational analysis seeks to identify common cancer alterations in specific malignancies (that is, known recurring mutations) that may inform patient prognosis or the use of a drug that targets a specific mutation. Conversely, whole genome or whole exome sequencing seeks to identify rare or previously uncharacterized mutations in the genome of a tumor that may reveal an unexpected vulnerability of this tumor to an existing targeted therapeutic. Whether such an approach will identify targetable alterations for many cancer patients or have a transformative impact in cancer care remains to be seen. For cancer patients whose tumors carry mutations that are targetable by an available therapy, whole-genome

sequencing clearly leads to better treatment, outcome, and survival. However, at this point, the number of cancer-causing mutations identified by DNA sequencing vastly exceeds the number of available treatments that specifically target tumors bearing these mutations.

Beyond these gene expression and genomics analyses stands a generation of novel diagnostic tools involving the science of proteomics, in which the spectrum of proteins expressed in a patient's tumor or serum will provide critical diagnostic information. The long-term goal of all these analytic techniques—both functional genomics and proteomics—is to assign each patient's tumor to a specific subtype of disease; such assignment may make it possible to apply drug therapies that are proven to be effective for treating a particular subtype of cancer but not other superficially similar tumors. Such tailor-made drug therapies hold the promise of yielding high response rates in narrowly defined patient populations.

To conclude, and on a more sober note, these various powerful tools of tumor stratification or subclassification may yield an "embarrassment of riches," that is, a vast number of distinct subtypes of human tumors whose diversity and distinctive properties greatly exceed our ability, in the near and distant future, to effectively develop treatments for most of these subtypes. After all, appropriate tailor-made therapies are usually validated in large and expensive clinical trials, as described later in Section 17.11. Moreover, as tumor types are sliced into increasingly thin sections, the number of patients affected by each subtype of tumor will grow correspondingly small, complicating attempts at recruiting enough patients to conduct clinical trials yielding statistically significant readouts. Thus, how will we possibly design and carry out clinical trials of diverse agents on diverse cancer subtypes? The answers to these quandaries are not yet in hand.

17.2 Surgery, radiotherapy, and chemotherapy are the major pillars on which current cancer therapies rest

An exclusive focus in this chapter on the newer, rationally designed agents would not be warranted because of one simple fact: the older treatments—surgery, chemotherapy, and radiotherapy—have been shown over many decades to be highly effective in extending the survival of cancer patients and even eradicating certain types of tumors with curative outcomes, whereas the newer, “rational” agents—whose design and implementation have been informed by the research described in this book—can rarely boast such successes. So, we begin this chapter with these older agents and describe their successes and failures.

The multi-step nature of cancer development, specifically the notion that primary tumors spawn metastases, has been a central concept in anti-cancer therapy since the end of the nineteenth century. Radiotherapy developed only slowly during the course of the twentieth century, and chemotherapy was initiated only after World War II. Through much of the century, then, surgery was the only form of therapy that offered any hope of reversing the disease, perhaps even achieving cures.

The discipline of surgical oncology embraced two notions as fundamental truths: small tumors will inevitably develop into large tumors and the resection of primary tumors represents an effective means of reducing the risk of metastatic relapse—the resurgence of disease long after the primary tumor has been removed. For example, resection of early-stage colorectal carcinomas yields 95% patient survival after five years—essentially a curative outcome—even without adjuvant (post-surgical) chemotherapy.

In fact, the accepted truths governing surgical practice were rarely subjected to critical tests until the last decades of the twentieth century, when the specialty of *outcomes research*, often referred to as evidence-based medicine, arose. The evidence in these cases came from clinical trials in which two or more alternative surgical strategies were compared with one another in randomized patient populations. These randomized trials revealed that some surgical procedures produced highly effective clinical outcomes, whereas others were of dubious utility, as described in **Supplementary Sidebar 17.2**.

Radiation oncology began soon after Wilhelm Röntgen's 1895 discovery of X-rays and the frequent observations soon thereafter that exposure to this form of electromagnetic radiation resulted in burn damage to normal tissues, including even tissue necrosis. The widespread use of radiotherapy in the oncology clinic awaited the development, after World War II, of the technical means of directing these rays in relatively narrow beams of radiation that were focused on diagnosed, clearly delineated tumors, almost invariably primary tumors. Focused adjuvant radiotherapy has become an essential clinical tool in reducing post-surgical relapse in the surgical field (that is, the tissues adjacent to or surrounding resected primary tumors). Indeed, nearly half of all cancer patients will receive radiation or radioactivity as a component of their therapy. A dramatic example of the utility of radiotherapy comes from post-lumpectomy (see **Supplementary Sidebar 17.2**) follow-up of older women with early-stage breast cancer: adjuvant (post-surgical) radiation reduces by 50% the rate of subsequent mastectomy (resection of the entire breast rather than just the area immediately around the tumor) during the decade following initial surgery.

The use of radionuclides—radioactive isotopes administered intravenously as components of a pharmaceutical drug or coupled to monoclonal antibodies—underlies systemic radiotherapy and is often used when all or parts of a tumor cannot be readily resected or when disseminated cancer cells need to be eradicated. Brachytherapy, involving the implantation of radioactive sources carried in small capsules into an organ site or tumor, is also used in a variety of cancers. Because brachytherapy does not generally reach uninvolved normal tissue, its use allows for the delivery of higher localized doses than those that are achievable by radiation with external beam therapy.

Chemotherapy has more recent origins: an often-related anecdote describes how the 1943 bombing of an American warship in the harbor of Bari, Italy, led to release of a large cloud of mustard gas of the sort used in World War I chemical warfare. Almost a thousand people died, sooner or later, from the effects of this explosion and the released cloud of gas. The clinical deterioration of some survivors of this catastrophe reawakened interest in the 1919 discovery that exposure to mustard gas leads to depletion of bone marrow cells and thus anemia. In fact, research begun independently at Yale University in 1942, a year before the Bari disaster, had revealed that intravenous doses of mustard gas—named after its characteristic odor—led to temporary regression of a lymphoma. We have encountered chemicals of this class in the form of alkylating agents (see Section 12.5) that are used, among other applications, to treat glioblastomas (see Table 17.1).

[Recall that in addition to their cytotoxicity, these alkylating agents are highly mutagenic, leaving the genomes of exposed cells with hundreds if not thousands of point mutations (see Figure 12.7B); this outcome reveals another side of a number of anti-cancer treatments: in addition to their effects in reducing or eliminating tumors, X-rays and certain cytotoxic agents are also carcinogenic, and their short-term successes in producing clinical remissions may be counterbalanced by the appearance years later of independently arising, second-site tumors that are direct consequences of their mutagenic actions.]

The transient clinical response of a lymphoma observed at Yale was followed by rapidly expanding interest in similar agents in the years that followed. The emphasis here was on cytotoxic agents that, for unknown reasons, killed neoplastic cells preferentially by sparing normal tissues, or at least by inflicting tolerable side effects on the patient. Almost always, discovery of the biochemical and cell-biological mechanisms of these drugs came decades after their introduction into the clinic, and in many cases, as discussed below, we still do not understand the precise mechanisms-of-action of a number of highly effective cytotoxic drugs.

By 1947, the utility of another class of cytotoxics was discovered, initially in the form of an agent for treating pediatric leukemias and lymphomas. In this case, the compound in question—aminopterin—acted as an antagonist of folate metabolism, inhibiting the formation of tetrahydrofolate and

thereby blocking some of the critical biosynthetic reactions that are required for the assembly of nucleotides and thus the synthesis of DNA and RNA. A young boy treated that year for lymphoma survived and lived another half century, representing the first documented cure of this disease.

Compounds like aminopterin are often termed antimetabolites because they interfere with the normal functioning of specific metabolites or the enzymes that produce them in the cell. Most of these agents closely resemble and are therefore chemical analogs of normal metabolites. For example, a number of highly effective antimetabolites are purine or pyrimidine analogs that operate either by preventing normal biosynthesis or by becoming incorporated into DNA, whose function they then inhibit (**Table 17.2**; **Figure 17.7**).

Table 17.2 Examples of antimetabolites used to treat cancer

Name	**Chemical structure**	**Targeted reaction**	**Examples of clinical use**
methotrexate	folate analog	formation of tetrahydrofolate	breast cancer, lymphomas
6-mercaptopurine	purine analog	purine biosynthesis	leukemia, NHL
doxorubicin	natural product[a]	intercalating agent, inhibits topoisomerase	wide range
thioguanine	guanine analog	purine biosynthesis	acute granulocytic leukemia

Name	Chemical structure	Targeted reaction	Examples of clinical use
fludarabine	purine analog	ribonucleotide reductase, DNA replication	chronic lymphocytic leukemia, NHL
cladribine	adenosine analog	adenosine deaminase	hairy-cell leukemia
bortezomib	peptide analog	proteasomal degradation	multiple myeloma
paclitaxel	natural product[a]	microtubule destabilization	lung, ovarian, breast cancer
etoposide	natural product[a]	DNA unwinding	lung cancer, sarcomas, glioblastoma
mitoxantrone	topoisomerase inhibitor	DNA unwinding	AML, breast cancer, NHL
irinotecan	topoisomerase inhibitor	DNA unwinding	colorectal carcinoma
vinblastine	natural product[a]	microtubule assembly	Hodgkin’s lymphoma

Name	Chemical structure	Targeted reaction	Examples of clinical use
vorinostat	hydroxamic acid	histone deacetylation	cutaneous T-cell lymphoma
azacitidine	pyrimidine analog	DNA methylation	myelodysplastic syndrome

Abbreviations: NHL, non-Hodgkin’s lymphoma; AML, acute myelogenous leukemia.

natural products

The molecular structures of ten different cytotoxic drugs. All contain ring structures and are relatively complex molecules. Temozolomide and cyclophosphamide are alkylating. Carboplatin is alkylating like. 6 mercaptopurine, fludarabine, and gemcitabine are nucleoside analogs. Etoposide and bortezomib are complex synthetic drugs. Paclitaxel and vincristine are natural products and have the most complex structures.

Figure 17.7 Cytotoxic drugs in current use The development of most cytotoxic drugs did not depend on detailed insights into the genetic and molecular mechanisms of tumor pathogenesis, but instead derived from investigations of the cytotoxic effects of a diverse array of organic molecules; most were products of synthetic organic chemistry, although a minority were natural products. These agents work in a number of distinct ways to kill cancer cells, although in many cases the precise mechanisms of cytotoxicity are not well understood. Temozolomide and cyclophosphamide alkylate DNA and generate lesions that are difficult to repair; carboplatin acts in a similar fashion but makes intra-strand cross-links within DNA. 6-Mercaptopurine interferes with nucleoside biosynthesis, whereas the cytotoxic actions of both fludarabine and gemcitabine seem to depend largely on the analogs of these nucleosides becoming incorporated into cell DNA, yielding nucleotides that are difficult to replicate or repair. Etoposide is a topoisomerase inhibitor; bortezomib disrupts proteasome function, whereas paclitaxel and vincristine function to stabilize and destabilize microtubules, respectively.

Another class of antimetabolites affects normal cell function by interfering with microtubule assembly, either inhibiting or fostering it. This class of drugs was one of the first useful categories of anti-cancer agents that were discovered through screens of libraries of natural products, that is, collected biochemical species produced by various plants, molds, and even animal species. Paclitaxel, initially named taxol, was discovered as the product of the Pacific yew tree, *Taxus brevifolia*. Its ability to block the breakdown of microtubules at the end of mitosis (see Figure 8.3) leads to potent therapeutic effects on a variety of commonly occurring tumors, including

those of lung, ovary, and breast, as well as head-and-neck squamous cell carcinomas.

Acting in the opposite direction are microtubule-depolymerizing agents that prevent assembly of microtubules, often by barring their interaction with the microtubule organizing centers (see Figure 12.38). One such agent is colcemide, which is often used experimentally to trap cells in the metaphase of mitosis, making karyotyping possible (see Figure 1.9). More useful clinically are vinblastine and vincristine, both derived from *Vinca rosea*, a periwinkle plant growing in Madagascar. The discovery in Canada in 1958 of this class of agents led to their frequent use in lymphomas, non-small-cell lung cancers, and breast cancers, as well as head-and-neck squamous cell carcinomas.

In 1965, yet another class of agents was uncovered that, like alkylating agents, induced covalent modifications of DNA, creating adducts that were not readily removed by cells' repair machinery. Cisplatin [*cis*-$PtCl_2(NH_3)_2$] was discovered serendipitously as an antibacterial agent that formed at platinum electrodes and subsequently showed potent anti-cancer activity. Like bifunctional alkylating agents, it generates covalent cross-links within DNA; certain alkylating agents form inter-strand cross-links, whereas cisplatin forms largely intra-strand cross-links, usually between two adjacent guanines. Prior to the advent of cisplatin and the related drug carboplatin, the cure rate for testicular cancer was in the range of 10%; these days, however, use of cisplatin and related agents leads to curing 90 to 95% of those suffering from this tumor.

OceanofPDF.com

Glossary

adjuvant
: (1) A treatment that is given in concert with or following another treatment. (2) A substance that is given together with an antigen to enhance the immune response. *See also* **neoadjuvant**.

lumpectomy
: Surgical procedure in which a tumor is removed together with immediately surrounding normal tissue while leaving the bulk of the affected organ intact; usually used in the context of breast cancer surgery.

external beam therapy
: Form of radiotherapy, in which the radiation source is usually a linear accelerator used as the source of radiation that is usually directed in a highly focused fashion to a region of tissue that is being treated.

antimetabolite
: Compound, typically used as an anti-tumor cytotoxic drug, that acts through its ability to interfere with the synthesis or function of a normal cellular metabolite.

natural product
: A chemical species that is a product of the natural metabolism of an organism, such as a bacterium, fungus, or plant.

head-and-neck cancers
: A group of carcinomas of the larynx, throat, mouth, nose, and salivary glands.

17.3 The present and future use of chemotherapy requires improved understanding of how anti-cancer drugs work

The discovery of these various cytotoxic drugs led repeatedly to confrontations with three major questions. First, how do they kill cancer cells? Second, why are certain types of cancer cells killed more readily than normal cells? And third, how do cancer cells and the tumors that they form develop resistance to agents that initially were effective in treating these tumors? These questions have been introduced into current studies of the more recent, molecularly designed agents that are the primary focus of this chapter.

In fact, for many of the cytotoxic drugs that have been in use for more than 70 years, answers to these questions remain elusive. Several mechanistic explanations of selectivity have been proposed (**Table 17.3**). The simplest—that cytotoxic drugs kill proliferating cells selectively—is hard to reconcile with the fact that the populations of cancer cells within most tumors actually have a very low proliferative index, that is, the proportion of cells residing in the active cell cycle.

Table 17.3 Known or suspected mechanisms of anti-tumor selectivity[a]

Name	Mechanism conferring selectivity
cyclophosphamide	detoxified by ALDH in normal bone marrow
cladribine	detoxified by non-hematopoietic cell types

Name	Mechanism conferring selectivity
taxol/paclitaxel	high proliferation index,[b] other mechanisms unknown
multiple cytotoxic drugs	high proliferation index,[b] high sensitivity to apoptotic stimuli
cisplatin	intact p53 function in testicular germ-cell tumors[c]
DNA-damaging agents	inability to halt cell cycle advance in response to DNA damage[d]
PARP inhibitors	defective homology-directed repair
DNA-damaging agents	various types of defective DNA repair

Abbreviations: ALDH, aldehyde dehydrogenase; PARP, poly(ADP-ribose) polymerase.

An alternative explanation is that specific chemotherapies target emergent tumor cell dependencies, that is, vulnerabilities that result directly from the specific lesions acquired by these cells en route to the malignant growth state. For example, tumor cells that develop from mutations in DNA repair pathways show enhanced sensitivity to unrepaired DNA damage incurred as a result of genotoxic chemotherapy. This emergent tumor cell vulnerability underlies the sensitivity of ovarian cancers bearing defects in the homologous recombination (HR) machinery to agents like cisplatin that induce DNA

cross-links usually resolved by HR-mediated DNA repair (see Section 12.9). Thus, existing genotoxic chemotherapies that are generally depicted as "non-targeted" (because they are not designed to attack a specific molecular target within a cell) may, in fact, target specific tumor cell dependencies. However, to this day, experts who are queried about (1) the mechanisms-of-action of many widely used agents, (2) why they selectively kill cancer cells, and (3) how tumors develop drug resistance readily admit to the minimal progress made in solving these fundamental questions.

Early on, medical oncologists (that is, oncologists who treat cancer with various drugs) recognized that drug resistance developed sooner or later for almost all the drugs and the cancer types under treatment, being manifested as the outgrowth of drug-resistant variant cell populations. This drug resistance was soon understood by applying the lessons learned from bacterial genetics, in which resistance to various types of antibiotic treatment was known to occur via the selective outgrowth of mutant variants, some of which may have already existed in bacterial populations prior to being challenged by drugs. Given the large numbers of cells in clinically detectable human tumors—almost 1 billion in a growth of 1 cm diameter—and the frequency of resistant mutants—perhaps one in a million—the emergence of drug-resistant variants seemed almost inevitable.

The response to this was the development of multi-drug protocols, often using combinations of drugs with distinct and complementary modes of cell killing, such as an antimetabolite, an alkylating agent, and a microtubule antagonist. In theory, the likelihood that variants preexisted in tumor cell populations that were simultaneously resistant to all three agents appeared to be astronomically low—the product of three probabilities, in this case one in 10^{18}. Indeed, the introduction of combination drug regimens resulted in dramatic and unprecedented clinical responses in certain tumors, even cures. For example, the ABVD regimen, which was developed in Italy in the mid-1970s and is still used to treat advanced Hodgkin's lymphomas (HLs), involves the administration of *a*driamycin (doxorubicin), a DNA-intercalating drug; *b*leomycin, a DNA-cleaving agent; *v*inblastine, a microtubule antagonist; and *d*acarbazine, an alkylating agent (**Table 17.4**). Depending on the stage at which the tumor is initially diagnosed, 5-year progression-free survival (PFS) of treated patients ranges from 85 to 98%, with many of these patients essentially cured of the disease. Another multi-drug protocol elicits

an almost 90% cure rate in childhood (younger than 15 years of age at diagnosis) acute lymphoblastic leukemia (ALL).

Table 17.4 Examples of multi-drug treatment protocols

Acronym	Components	Mechanisms of action	Application
ABVD	doxorubicin, bleomycin, vinblastine, dacarbazine	intercalation, DNA strand breaks, microtubule inhibition	Hodgkin's lymphoma
CHOP	cyclophosphamide, hydroxydaunorubicin, vincristine, prednisone	alkylating, DNA intercalation, microtubule inhibition, steroid antagonist	non-Hodgkin's lymphoma
FOLFOX	fluorouracil, leucovorin, oxiplatin	pyrimidine analog, folic acid antagonist, DNA cross-linking	colorectal cancer
TIP	paclitaxel, ifosfamide, platinum agent cisplatin	microtubule antagonist, alkylating, DNA cross-linking	testicular cancer

In spite of these occasional striking successes, no fixed rules emerged to help in the rational design of multi-drug therapy, aside from the intuitive notion that drugs with distinct mechanisms of cytotoxicity are likely to function in complementary and thus synergistic ways. Indeed, it is unlikely that cancer cell populations will readily spawn variants that can simultaneously resist the cytotoxic effects of multiple agents that act through multiple unrelated mechanisms. During the course of early clinical trials, the initial implementation of these combination regimens has been guided more by issues of toxicity rather than by drug mechanisms-of-action. Individual chemotherapies elicit a diverse set of so-called “side effects,” including uncontrollable diarrhea; peripheral neuropathy; kidney, liver, and cardiac toxicity; and bone marrow suppression (**Sidebar 17.4**). Although combinations of agents that induce similar side effects lead to potentially lethal levels of organ-specific toxicity that limit overall drug dose and efficacy, combining agents with distinct toxicities allows for the administration of higher total drug concentrations. However, this strategy of concomitant application of three or four agents also often leads to unacceptable levels of systemic toxicity.

Sidebar 17.4 Do combination chemotherapies represent a double-edged sword?

Many decades after these multi-drug therapies were first contrived, we still do not understand why and how they work. Some recent studies even suggest that the use of multi-drug regimens may serve to treat heterogeneity within populations of patients instead of heterogeneity within individual tumors. Specifically, these observations indicate that distinct components of these multi-drug regimens are effective in specific patient subpopulations and that the observed utility of combination regimens derives from their ability to provide a uniform therapy to a diverse set of tumors. If this were the case, it would suggest that these regimens are inherently “de-personalized,” that is, being applied to a heterogeneous group of patients rather than being designed specifically for an individual patient under treatment.

The potential dangers of “de-personalized” medicine are twofold. First, patients are exposed to the certain toxicity of all administered drugs, although realizing the benefit of only a subset of them. The side effects of such

regimens include acute toxicity and the aforementioned increased cancer risk, but they can also include long-term impacts on development and health that are only manifest years after treatment (**Figure 17.8**). Second, standard, de-personalized treatments are administered to patients regardless of the presence of any specific tumor biomarkers and resulting association of successful treatments with specific subsets of tumors. This patient-agnostic approach to cancer treatment, when such treatments are the standard of care for a malignancy, can impede the development of improved therapies tailored to the particular clinical needs of specific subsets of these patients. As a consequence, largely effective but toxic combination therapies can become entrenched in clinical practice as obligatory front-line therapies, discouraging attempts to identify subsets of patients who might respond better to alternative treatments. Thus, the drug regimens that historically represented the first major advances in cancer treatment now may represent major barriers to improving cancer treatment and long-term patient health.

A photo of two women with blonde hair standing with their arms over each others shoulders.

Figure 17.8 The great success and long-term consequences of high dose therapy The photograph shows identical 26-year-old twins. The twin on the right was treated for childhood B-cell acute lymphoblastic leukemia at 4 years of age. She received high-dose combination chemotherapy in addition to cranial radiation. Although this treatment is frequently curative, as it was in this case, 25 years following combination therapy, 27.5% of adult survivors of childhood treatment suffer from at least one severe, life-threatening, or disabling condition (in comparison with 5.2% of siblings of a comparable age). (Adult Primary Care after

Childhood Acute Lymphoblastic Leukemia, *The New England Journal of Medicine*, Oct. 13, 2011; 365:1417-1424, DOI: 10.1056/NEJMcp1103645.)

An understanding of the specific mechanism-of-actions of chemotherapeutic drugs has perhaps become even more relevant as these drugs are given as adjuvant treatments administered together with novel immunotherapies. A well-established example of this is the use of the anti-CD20 antibody Rituximab in combination with multi-drug regimens in the treatment of B-cell leukemia. More recently, cyclophosphamide (see Table 17.1) is given to patients with treatment-refractory B-cell malignancies prior to CAR-T therapy (see Chapter 16). As the use of immunotherapy regimens expands, it will become increasingly important to understand the mechanisms by which our current arsenal of chemotherapeutic agents modulate both tumor cell immunogenicity and the immunocyte responses to immune-targeting agents.

In contrast to these hematopoietic malignancies, the response rates of most solid tumors to multi-drug chemotherapy regimens are usually limited by intrinsic (that is, preexisting) tumor resistance to therapy (**Table 17.5**). Nonetheless, these agents can be effectively employed as neoadjuvant treatments, that is, treatments that are applied *prior* to surgery to debulk a solid tumor or to shrink its borders to a size or configuration that render surgical excision more effective (see Figure 17.2). Chemotherapy is also applied as adjuvant therapy following surgery in order to eliminate residual, non-excised tumor cells. The benefits of both neoadjuvant and adjuvant therapy are clearly established when comparing the survival of patients treated in combination with surgery. However, cytotoxic chemotherapies, when applied on their own, are rarely successful in the treatment of solid tumors.

Table 17.5 Mechanisms of acquired resistance to anti-cancer therapies[a]

Nature of resistance	**Mechanism of resistance**
Multi-drug resistance[b]	increased expression of drug export pumps
Pan-drug resistance[c]	unknown
Drug detoxification[d]	enzymatic detoxification of drug molecule
Acquired drug resistance	refuge of cancer cells in drug-protected anatomical sites[e] failure of tissue to convert pro-drug into active form refuge of cancer cells in an anatomical site that provides protective trophic signals[f] massive stromalization[g] emergence of mutant, structurally altered cellular target[h] amplification of gene encoding targeted protein emergence of cells bearing alterations in genes whose products are functionally redundant with drug target [i]

Nature of resistance	Mechanism of resistance
	loss of drug importer [j] passage through an EMT [k] activation of anti-apoptotic regulators
Physiological activation of compensatory adaptive mechanisms	
Resistance to EGF-R inhibition	up-regulation of IGF-1R signaling amplification of *Met* gene mutational activation of a *ras* pathway gene cell state changes, including conversion from non-small-cell to small-cell lung cancer
Resistance to Bcr-Abl inhibition	amplification of *Bcr-Abl* gene drug target site mutations in *Abl* blast cell transition

Chemo-refractory tumor cell populations invariably arise in patients at rates far higher than would be predicted from the measured frequencies of variant cells that are intrinsically resistant to specific drugs. Precisely why they do so is often a puzzle. One explanation derives from the commonly observed trait of multi-drug resistance displayed by many types of cancer cells and achieved by the actions of single cancer cell-associated genes and encoded

proteins; the latter often function as plasma-membrane export pumps that actively extrude multiple molecular species and thus multiple distinct types of drug molecules from cells under treatment. We can also imagine that cancer cell alterations that weaken or cripple the pro-apoptotic machinery (for example, p53 inactivation, see Section 9.9) can likewise confer concomitant resistance to multiple cytotoxic drugs.

The need to test drugs and administer them with maximum therapeutic effect led in the mid-twentieth century to the emergence of an entirely new discipline focused on the pharmacology of anti-cancer therapeutics. Thus, pre-clinical drug testing directed toward studying the effects of candidate drugs on both cultured tumor cells and tumor xenografts growing in laboratory mice became the prelude to a sequence of clinical tests on human subjects designed to gauge the toxicity and tolerability of drugs, their utility in treating specific subtypes of neoplastic diseases, and ultimately, their efficacy.

Study of the pharmacokinetics (PK) of drugs revealed it as a critical determinant of therapeutic efficacy, being governed by the rates at which an administered drug is (1) absorbed into the circulation, as gauged by its concentrations in the plasma; (2) distributed in different physiological compartments throughout the body; (3) metabolized in ways that either potentiate or inactivate its intended function; and (4) excreted.

Still, these complex PK responses cannot predict the kinetics with which cells or molecular targets actually *respond* to administered drugs—the study of pharmacodynamics (PD). Thus, independent of the rates of drug accumulation in a tissue or within cells, are the cellular processes that govern the kinetics of cellular responses to treatment including the kinetics of changes in specific biochemical processes. For example, if the cytotoxic effects of taxol depend on its ability to stabilize microtubules within cancer cells, how quickly can actual microtubule growth in these cells be observed following initial drug administration and how rapidly do cytostatic and cytotoxic effects on cancer cells follow? Notably, the biological effects of agents like taxol depend on drug dose, so the pharmacokinetics and pharmacodynamics of anti-cancer agents are closely interrelated.

In principle, the properties of the mechanism-based drugs that are described in the following sections should provide ready answers to the three questions posed earlier, that is, (1) How does each drug kill cancer cells? (2) Why are its actions selective for neoplastic tissues? And (3) how do tumors develop drug resistance after an initial period of responsiveness? In reality, in spite of the extraordinary level of detail known about these rationally designed agents, our ability to answer these questions is often limited.

Glossary

selectivity
: Relative ability of a therapy to affect targeted cells or tissue compared with its (side) effects on non-targeted normal cells or tissue. *See also* **therapeutic index**.

peripheral neuropathy
: Damage to peripheral nerves, usually in the limbs, that affects muscle coordination or sensation and may even create sensed pain.

neoadjuvant
: Referring to a treatment that is undertaken before the main therapy is applied, e.g., to reduce tumor size before surgery. *See also* **adjuvant**.

chemo-refractory
: Resistant or unresponsive to treatment by chemotherapy.

multi-drug resistance
: Development by cancer cells under treatment of concomitant resistance to multiple chemically distinct species of therapeutic drugs.

pharmacokinetics
: Results of measurements gauging the rise and fall in the concentration of an administered drug in the body, usually measured in the plasma and gauged at different times after initial administration.

pharmacodynamics
: Time course of biological responses within a tissue or its cells that are induced by a drug, usually gauged at different times after initial administration.

- cIntact p53 function is known to render these cells highly susceptible to DNA damage–induced apoptosis.Return to reference c
- dDefective p53 function, as well as nonfunctional cell cycle checkpoints, is presumed to allow cells bearing damaged, still-unrepaired genomes to advance into S phase, M phase, or both, resulting in stalled replication forks or mitotic catastrophe.Return to reference d
- aThe entries in this table refer to tumors that are initially responsive to an applied therapy and then exhibit resistance that is manifested as regrowth of a tumor and thus indicates clinical relapse. Resistance may emerge because of the outgrowth of a therapy-resistant subpopulation of variant cells; such variant cells may preexist in the population prior to the onset of treatment or may arise as genetic or epigenetic variants that are formed *de novo* during the course of treatment. Alternatively, resistance may arise as a normal compensatory physiological response to an initially applied therapy-imposed inhibition; this second form of resistance presumably occurs widely throughout a tumor rather than resulting from the selective outgrowth of a therapy-resistant subpopulation.Return to reference a
- bAs an example, concomitant resistance to paclitaxel, doxorubicin, etoposide, and vinblastine is exhibited by cells overexpressing P-

glycoprotein, a drug export transporter operating in the plasma membrane.Return to reference b

- cPan-drug resistance refers to resistance against all agents that are applied to a tumor and cannot be attributed to increased drug export.Return to reference c
- dAs an example, lack of responsiveness of glioblastomas to the temozolomide alkylating drug often results from expression of the MGMT enzyme, which detoxifies it (see Section 12.7).Return to reference d
- eAs an example, a variety of metastatic growths in the brain may be protected from chemotherapy by the blood–brain barrier, which blocks agents in the circulation from entering the brain parenchyma.Return to reference e
- fAs an example, lymphoma cells may survive in the thymus because thymic stromal cells release survival factors in response to the genotoxic stress provoked by chemotherapy.Return to reference f
- gAs an example, part of the difficulty of treating pancreatic carcinomas derives from the development in these tumors of a highly desmoplastic stroma that impedes transport of drugs from the circulation to the neoplastic cells.Return to reference g
- hAs an example, patients treated successfully with imatinib/Gleevec will develop drug resistance because of the emergence of cells expressing a mutant, structurally altered Bcr-Abl protein that no longer permits high-affinity binding of the drug.Return to reference h
- iAs examples, individuals whose tumors exhibit responsiveness to EGF-R inhibitors may develop resistance because of the mutational activation of a *ras* oncogene or because of *crkl* amplification. Resistance of CML cells to imatinib/Gleevec may develop because of the emergence of cells expressing altered $p19^{ARF}$, Myc, p53, or Ras, which function to bypass the dependence of the tumor cells on the targeted Bcr-Abl oncoprotein. Resistance to B-Raf inhibition can develop through up-regulation of PDGF-Rβ expression or N-*ras* mutation.Return to reference i
- jHigh-grade serous ovarian carcinomas are often treated with doxorubicin that is encapsulated in a synthetic liposome. Drug-resistant cells often emerge that have lost the LDL receptor–related

protein (LRP1B), a cell surface protein that appears to be responsible for internalizing the liposomes.Return to reference j

- kPassage through an epithelial–mesenchymal transition (EMT) results in, among other changes, the expression of drug efflux pumps in the plasma membrane and increases in expression of anti-apoptotic proteins.Return to reference k

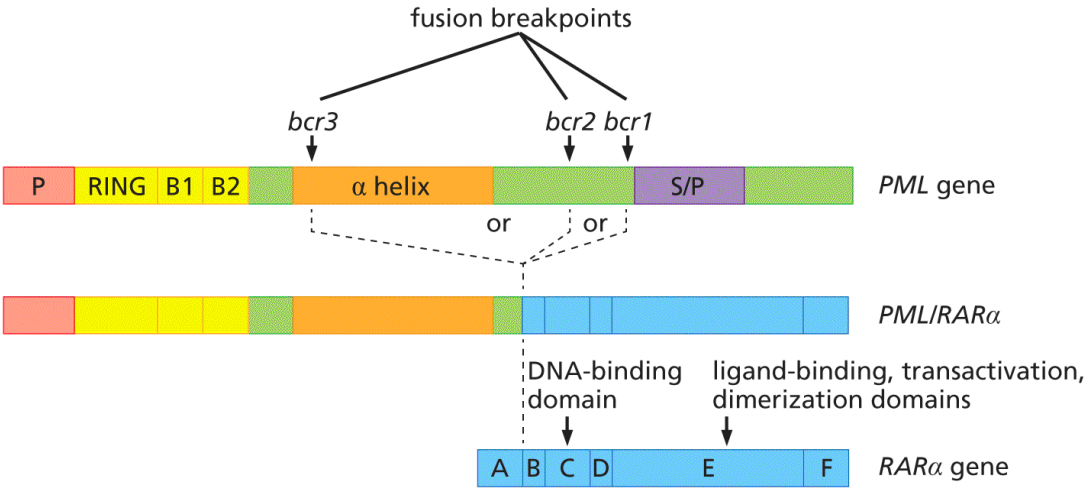
17.4 Differentiation, synthetic lethality, and cell cycle checkpoints can be exploited to kill cancer cells

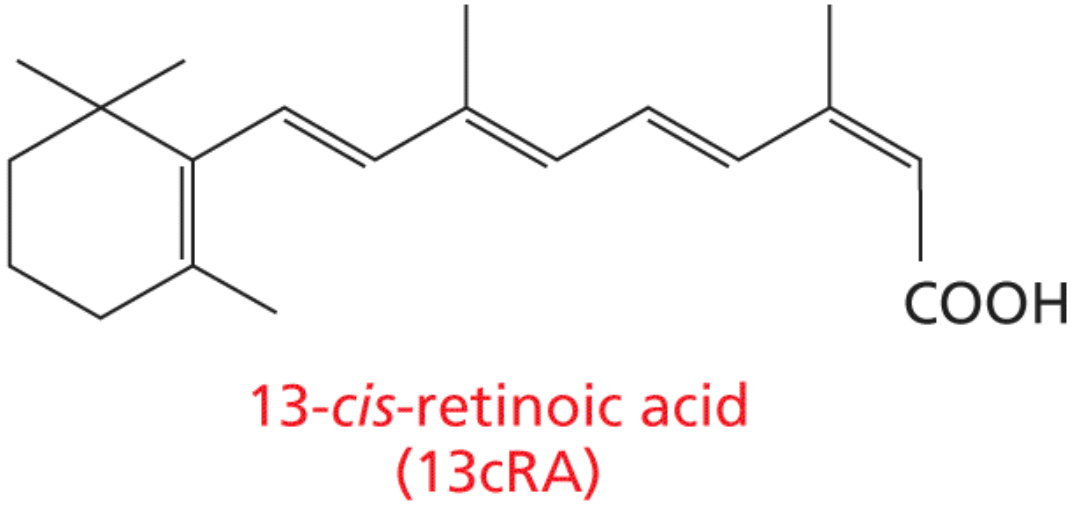
In principle, several distinct biological strategies might prove to be equally successful in eliminating established tumors or holding their growth in check. The most obvious of these are designed to induce the death of cancer cells, usually via apoptosis. Indeed, almost all existing nonsurgical strategies for eliminating cancer cells lead in one way or another to activation of the apoptotic pathways described in Chapter 9. However, an alternative therapeutic strategy relies on inducing differentiation, and we will consider this one first, if only briefly.

As described in Chapter 8, the acquisition of the malignant phenotype is usually accompanied by defective differentiation and the associated entrance into a post-mitotic state. Recall that as tumor cell populations evolve to greater degrees of malignancy, they usually shed more and more markers of differentiation. These behaviors suggest an attractive strategy for treating tumors: persuade cancer cells to differentiate and thereby enter into post-mitotic states. Although we have learned much about the connections between cell cycle control and the regulation of differentiation programs (see Sections 8.9 and 8.11), most of this information has not yet been translatable into effective forms of therapy. The prominent exception has come from one form of treatment of acute promyelocytic leukemia (APL) (**Figure 17.9**). In the course of this therapy, the undifferentiated leukemic blast cells can be induced to differentiate into neutrophils by treatment with all-*trans*-retinoic acid (ATRA). Treatment of APL patients with ATRA together with concomitant chemotherapy often results in complete remission, with five-year survival rates approaching 75 to 85%—suggestive of complete cures.



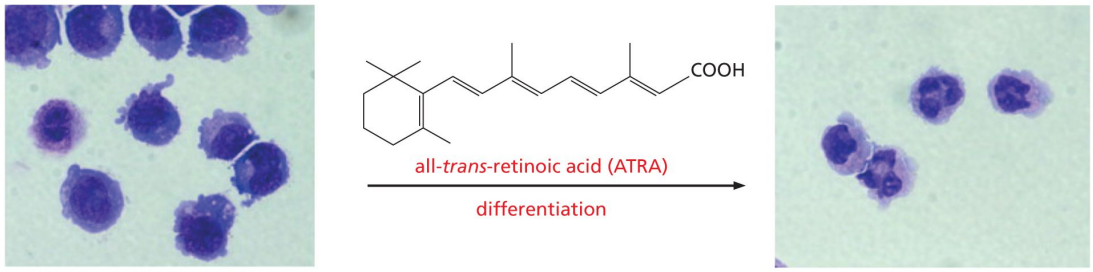
A diagram shows three fusion break points in a P M L gene. B c r 3 occurs in the alpha helix domain and b c r 2 and b c r 1 occur in a green domain. Everything to the left of the breakpoint is then attached to a R A R alpha gene to form P M L slash R A R alpha. the R A R alpha gene contains D N A binding, ligand-binding, transactivation, and dimerization domains.

(A)



The molecular structure of 13 cis retinoic acid or 13 c R A. The structure consists of an 8 carbon chain with alternating single and double bonds. Carbon 1 is bonded to a cyclohexene ring that has three methyl groups. Carbon 3 and carbon 7 are bonded to methyl groups. Carbon 8 is bonded to a carboxyl group.

(B)



Two micrographs shows how all-trans-retinoic acid or A T R A treatment causes promyelocytes to differentiate into polymorphonuclear cells also known as neutrophils. The promyelocytes are almost completely dark purple. The neutrophils are a mixture of light and dark purple. The molecular structure of all trans retinoic acid consists of an 8 carbon chain with alternating single and double bonds. Carbon 1 is bonded to a cyclohexene ring that has three methyl groups. Carbon 3 and carbon 7 are bonded to methyl groups. Carbon 8 is bonded to a carboxyl group.

(C)

Figure 17.9 Retinoic acid and induced differentiation of cancer cells (A) In >95% of acute promyelocytic leukemia (APL) cases, a translocation involving Chromosomes 15 and 17 results in fusion of the gene encoding the retinoic acid receptor (RARα, also termed RARA) with the promyelocytic leukemia (*PML*) gene. The *PML* gene can undergo fusion with the *RARA* gene in any of three sites, termed breakpoint cluster regions (bcr1,2,3). The fused portion of RARα retains the DNA-binding domain (region C) and the ligand-binding domain (region E). Once formed, the resulting fusion protein appears to block the differentiation of promyelocytes into various granulocyte cell types, which normally depends on the actions of retinoic acid (RA) binding to its receptor, RARα. (B) Large numbers of promyelocytes carrying many granules in their cytoplasm are apparent in the circulation (*left*) of an individual suffering from APL. However, following all-*trans*-retinoic acid (ATRA) treatment, these immature promyelocytes disappear and are replaced by differentiated granulocytes, specifically polymorphonuclear (PMN) neutrophils (*right*). ATRA causes inactivation and degradation of the PML-RARα fusion protein, allowing the normal RARα to drive normal differentiation. (C) 13-*cis*-Retinoic acid has been used to cause regression of the premalignant precursors of head-and-neck carcinomas. (A, adapted from S. Kalantry et al., *J. Cell Physiol*. 173:288–296, 1997. With permission from John Wiley & Sons. B, Reprinted from Blood, 107 (8), Beatrice U. Mueller, Thomas Pabst, José Fos, Vibor Petkovic, Martin F. Fey, Norio Asou, Ulrich Buergi, Daniel G. Tenen, ATRA

resolves the differentiation block in t(15;17) acute myeloid leukemia by restoring PU.1 expression, 3330-3338, Copyright 2006, with permission from Elsevier.)

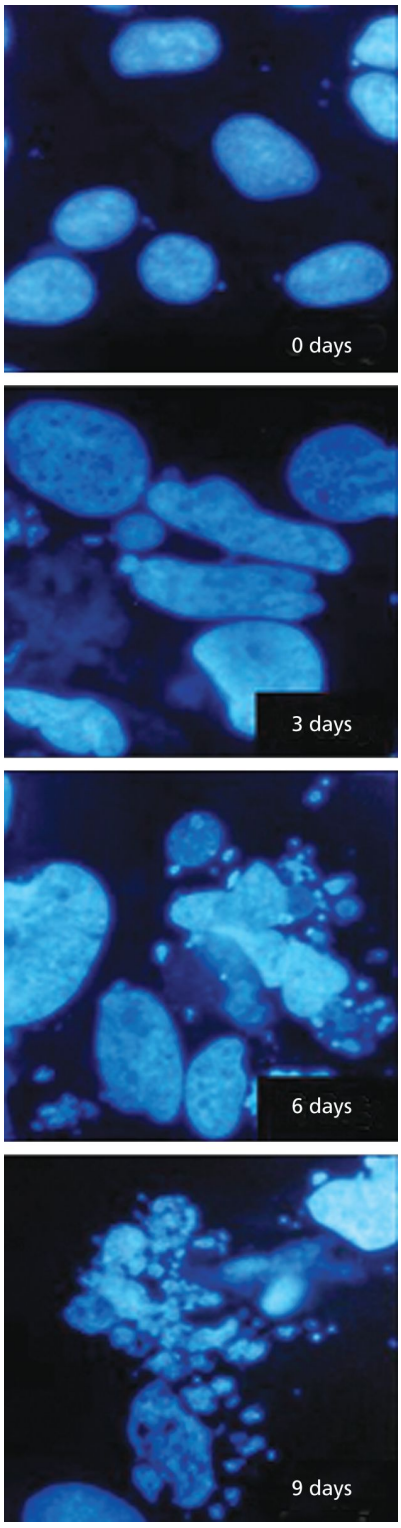
During the initial development of APL, the normal differentiation program of certain hematopoietic cells is blocked by the actions of the fusion protein PML-RARα, which results from a 15;17 chromosomal translocation seen in the leukemic cells of almost all APL patients (Figure 17.9A). This hybrid protein is composed of the PML (promyelocytic leukemia) protein, which has multiple normal functions, some associated with tumor suppression, fused to the nuclear retinoic acid receptor (RARα) protein. The latter, upon binding its retinoic acid (RA) ligand, is normally able to induce the expression of genes that program cell differentiation in a variety of cell types throughout the body (see Section 5.8). [In the absence of ligand, RARα recruits histone deacetylases (HDACs), which cause repression of differentiation-associated genes, whereas in the presence of RA ligand, RARα recruits histone acetyltransferases (HATs) that permit expression of these same genes; see Section 1.8.]

In fact, the precise mechanism by which the PML-RARα protein prevents the differentiation of promyelocytic leukemia cells is not clear. An attractive possibility is that the PML-RARα fusion protein found in leukemic cells interferes with the differentiation-inducing functions of the normal RARα in bone marrow cells, thereby causing accumulation of large numbers of these cells in a stem cell-like state. [The ligand-activated RARα acts to induce expression of certain target genes associated with the differentiation of hematopoietic precursor cells, whereas the PML-RARα fusion protein acts as a repressor, or at least an antagonist, of RARα. This interference with the normal RARα function seems to derive from the ability of the PML-RARα complex to bind more avidly to the HDAC co-repressor complex (see Section 1.8) than does the normal RARα.] Much of the therapeutic effect of all-*trans*-retinoic acid treatment appears to derive from its ability to cause the PML-RARα complex to release its grip on HDACs and to induce subsequent ubiquitylation and proteasome-mediated degradation of the PML-RAR fusion protein, resulting in relief of the block to differentiation. A complementary treatment derives from the use of arsenic trioxide (ATO), first discovered in China, which also drives degradation of PML-RARα; when applied together with ATRA, the two agents achieve a greater than 90% cure rate of APLs. Arsenic is usually portrayed as a highly toxic poison, whereas in this case it is clearly a remarkable lifesaver!

A similar mechanism likely explains the successes of the therapy that employs 13-*cis*-retinoic acid (13cRA; see Figure 17.9C), related chemically to vitamin A and to the all-*trans*-retinoic acid described above. It has been used with great success to cause the regression of pre-malignant lesions in the mouth and throat, thereby preventing or delaying their progression to head-and-neck cancers. Interestingly, loss of expression of RARβ—a second, similarly functioning RA receptor—is often observed in these

pre-malignant growths, as well as in a variety of other human carcinomas, ostensibly because its loss helps the cells in these various lesions to avoid entrance into a differentiated, post-mitotic state. Moreover, reduction of RARβ receptor expression in mice, achieved through the use of an antisense transgene, results in the formation of large numbers of lung carcinomas by 18 months of age, providing further support for the notion that evasion of retinoic acid-induced differentiation serves as an important mechanism of carcinoma pathogenesis.

Beyond these two striking examples, strategies that induce differentiation have had limited success in treating established cancers. An alternative set of therapeutic strategies takes advantage of the vulnerabilities that cancer cells have once they have discarded critical checkpoint controls operating in the normal cell cycle (see Table 17.3; Section 8.1). For example, some cancer cells lack the checkpoint control that normally blocks entrance into mitosis (M phase) from the G_2 phase until significant damage to the genomic DNA or to the chromosomes has been repaired. Consequently, many neoplastic tissues may be treated by inflicting genomic damage through chemotherapeutics or radiation. Whereas normal cells will tarry and repair this damage before advancing into M phase, cancer cells may ignore such damage and proceed blithely into mitosis, where they may stumble into a mitotic catastrophe that threatens their continued viability when they attempt to segregate their still-damaged chromosomes (**Figure 17.10**). This damage may be so overwhelming that it succeeds in triggering the residual apoptotic responses that these cells possess.



Four fluorescence microscopy images show the effect of chemotherapy on cancer cells over a period of 9 days. On day 0, the cells are ovular, almost like fingerprints. On day 3, the cells are elongated and slightly splotchy. On day 6,

some of the cells are breaking up into pieces. On day 9, only a couple cells remain that are not completely fragmented.

Figure 17.10 Chemotherapy and mitotic catastrophe Many chemotherapeutic drugs may damage the chromosomes of cancer cells. Because some cancer cells lack key G_2/M checkpoint controls, they may advance into mitosis without having repaired the chromosomal damage. This may cause them to enter into "mitotic catastrophe," which results in aneuploidy, polyploidy, formation of micronuclei, and the eventual death of these cells. Seen here are the effects of low doses (50 ng/ml) of doxorubicin, a widely used chemotherapeutic drug, on Huh-7 human hepatoma cells. Over a period of nine days, the nuclei of these cells grow larger or smaller and many eventually fragment into micronuclei, each of which carries a small number of chromosomes; this leads eventually to cell death, often by apoptosis. (From Y.W. Eom et al., *Oncogene* 24:4765–4777, 2005. With permission from Nature.)

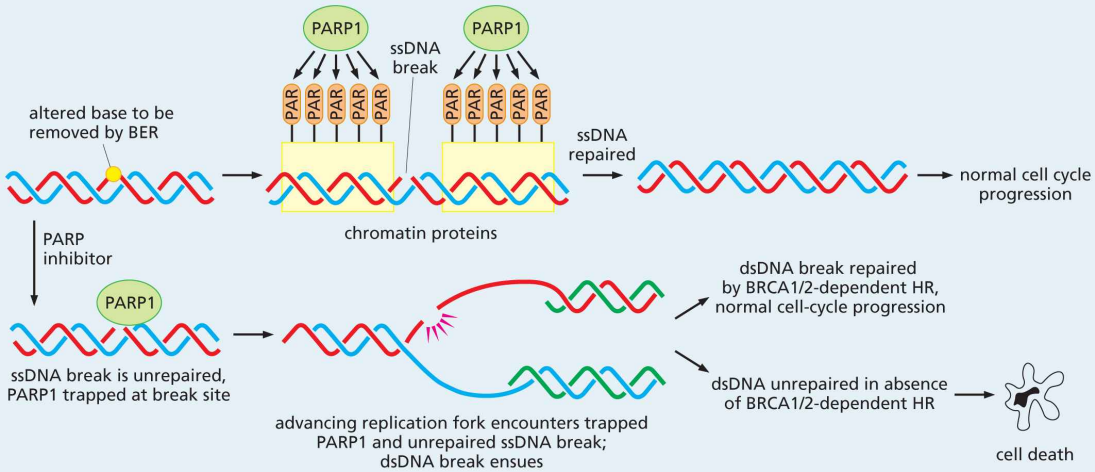
Similarly, cancer cells that lack the ability to undergo a G_1 phase cell cycle arrest following the induction of DNA damage, as is seen in the absence of the p53 tumor suppressor, become highly dependent on G_2 /M phase cell cycle arrest to avoid such a mitotic catastrophe. In this context, small molecules that target mediators of this G_2 /M phase cell cycle arrest, including the ATM and MK2 checkpoint kinases, can specifically sensitize p53-deficient tumors to chemotherapy (**Supplementary Sidebar 17.5**). Such an interaction can be viewed as a synthetic lethality, as it represents a therapeutic strategy in which a tumor cell-specific alteration, while conferring growth-enabling characteristics upon tumor cells, also recreates an emergent targetable tumor cell vulnerability (**Sidebar 17.5**.)

Sidebar 17.5 Targeting DNA repair deficiencies

In addition to targeting cell cycle dependencies that emerge during tumorigenesis, synthetic lethal approaches are also currently used to target tumor-specific alterations in DNA damage response pathways. Thus, breast and ovarian cancers that are deficient for either the *BRCA1* or *BRCA1* gene products represent perhaps the most notable examples of this therapeutic approach. The BRCA1 and BRCA2 proteins are necessary to perform homologous recombination and repair (HR) following the induction of a DNA double-strand break. In cells lacking either *BRCA1* or *BRCA2*, the high level of unrepaired DNA breaks fuels genomic instability and, in turn, the acquisition of pro-tumorigenic genetic alterations (see Section 12.10).

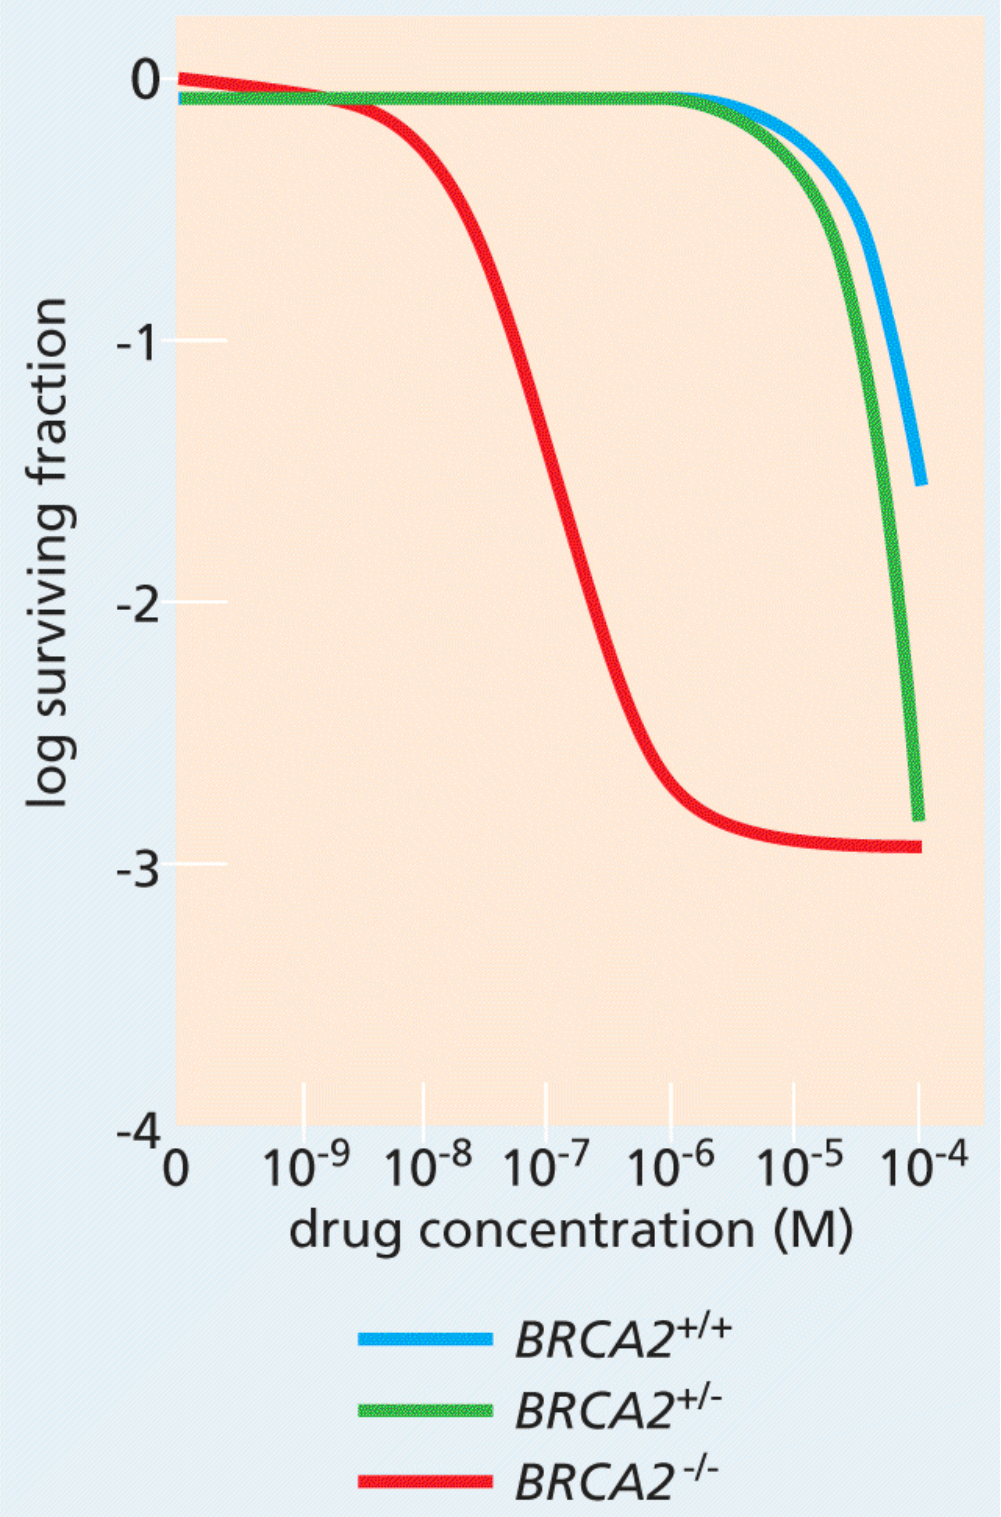
However, the absence of these repair proteins also creates a *de novo* dependency on other DNA repair factors that can compensate, at least in part, for this ongoing

genomic instability through their own abilities to support minimal levels of genomic integrity and tumor cell survival. In this context, impairment of such backup compensatory repair pathways can render a cell vulnerable to a synthetic lethality. Thus, cells routinely suffer single-strand breaks in their DNA, which trigger ADP-ribosylation by PARP1 of nearby histone and non-histone chromatin proteins in anticipation of break repair; in the absence of functional PARP1, such damage goes unrepaired. When a replication fork subsequently encounters such an unrepaired single-strand break, a collapsed replication fork ensues, resulting in a double-strand break that can only be effectively repaired by HR mediated by BRCA1–BRCA2 associated complexes. Without such repair, these dsDNA breaks create cell lethality. This explains why PARP1 inhibitors are preferentially toxic to cells lacking *BRCA1* or *BRCA2* (**Figure 17.11**).



A diagram shows the effect of PARP 1 in a cell. The process starts with an altered base in a section of double stranded D N A that is removed by B E R. This results in a single stranded D N A break. PARP binds to either side of the break and stimulated the addition of PAR proteins and other chromatin proteins. The single strand D N A is repaired and normal cell cycle progression occurs. However, if a PARP inhibitor is present, the single strand D N A break is unrepaired and PARP 1 is trapped at the break site. The advancing replication fork encounters the trapped PARP 1 and unrepaired single strand D N A break and a double strand D N A break ensues. If the break is repaired by B R C A 1 or 2 dependent H R, normal cell cycle progression occurs. If the break is unrepaired due to an absence of B R C A 1 or 2 dependent H R, cell death occurs.

(A)



A line graph of the log surviving fraction of three different cell lines relative to the drug concentration. All three cell lines have a log surviving fraction close to 0 when the drug concentration is low. Around 10 to the negative 8 molar, the log surviving fraction of B R C A 2 minus minus decreases rapidly

to around negative 3. Around 10 to the negative 5 molar, B R C A 2 plus plus and B R C A plus minus start to decrease rapidly with B R C A plus minus decreasing slightly faster.
(B)

Figure 17.11 PARP1 inhibition promotes DNA damage and cell death in BRCA1/2 deficient cells (A) Altered bases are removed by base-excision repair (BER); the resulting abasic sites are then converted to ssDNA breaks (SSBs). PARP1 binds to these breaks and catalyzes the addition of PAR polymers on itself (auto-PARylation), as well as flanking histones and other chromatin-associated proteins. This process promotes chromatin relaxation and the recruitment of DNA repair proteins. PARP inhibitors block PARylation of PARP1 itself and neighboring proteins. As a result, PARP1 fails to disassociate from the SSB, resulting in its being trapped on DNA and the persistence of unrepaired SSBs. When an advancing replication fork encounters the SSB, a double-strand break (DSB) is generated. (B) Proper repair of the resulting DSB requires BRCA1, BRCA2, and other homologous recombination (HR) proteins. Consequently, in the absence of HR repair proteins (like BRCA1 or BRCA2), tumor cells are highly sensitized to PARP inhibitors (PARPi) (*lower right*). The specific absence of BRCA2 in tumor cells, and not in non-malignant cells, provides a therapeutic window for PARPi use. (B, from H. Farmer et al., *Nature* 434:917-921, 2005. With permission from Nature.)

This specificity toxicity provides a therapeutic window in which only HR-defective tumor cells, and not adjacent normal cells, are sensitive to PARP1 inhibition. Further evidence for the specific interaction between *BRCA1/2* genes and PARP inhibitor sensitivity comes from the analysis of tumors following their extended treatment with PARP1 pharmacologic inhibitors and eventual escape from this treatment, leading to clinical relapse. Such PARP1 inhibitor-resistant tumors frequently eliminate the *BRCA1* exon containing frame-shift mutations that lead to protein inactivation and loss. As a result, functional BRCA1 protein is restored, together with double-strand break repair capacity.

More generally, genotoxic chemotherapies that increase the burden of DNA damage in cancer cells may further exploit the vulnerabilities present in DNA repair- and checkpoint-defective cells. Indeed, many of the traditionally used cancer therapeutics are suspected to take advantage of defects in checkpoint controls to destroy cancer cells, but sufficient evidence to guide the use of these agents in specific cancers is not yet in hand. In the discussions that follow, however, we will focus on agents that target specific critical proteins rather than the genomes of cancer cells.

OceanofPDF.com

Glossary

blast
: Term used as prefix or suffix, indicating a relatively undifferentiated or embryonic precursor cell.

remission
: Retreat or disappearance of a disease state with the implied possibility of its eventual reappearance or worsening.

mitotic catastrophe
: Process by which unrepaired damage to DNA or chromosomes or mis-segregation of chromosomes causes cells to enter into M phase and die there through non-apoptotic mechanisms because of an inability to properly complete the critical final steps of mitosis.

synthetic lethal
: (1) Describing phenotypes that result from the combined effects of two alleles, each of which is nonlethal on its own, but which, when present in combination, result in lethality. (2) Referring to a state in which an existing genetic or epigenetic condition renders a cell vulnerable to killing by one or another applied agent, such as a therapeutic agent.

OceanofPDF.com

17.5 Functional and biochemical considerations dictate that only a subset of the defective proteins in cancer cells are attractive targets for drug development

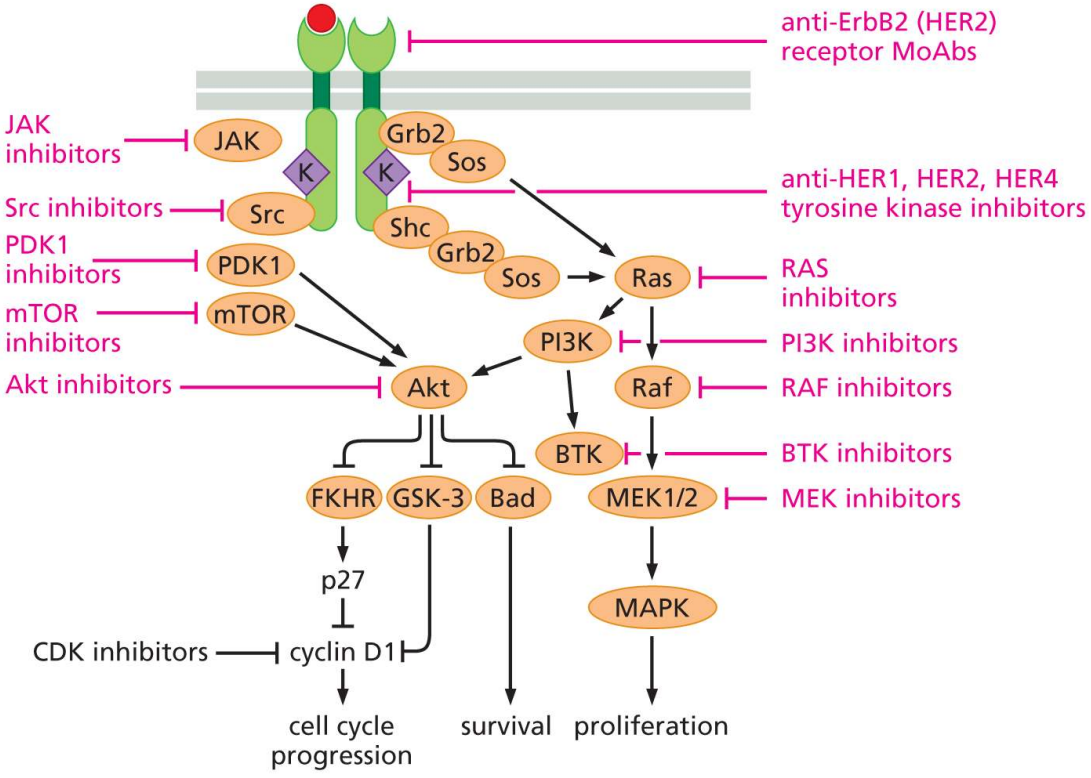
In the past (see Section 17.2), anti-cancer drugs were discovered and optimized for their cytotoxic effects on cancer cells (and thus on tumors as a whole) without any preconception as to precisely how these drugs were killing cancer cells. The mindset of current anti-cancer drug developers, in contrast, is far more focused: to direct therapeutic drugs at specific molecular targets within cancer cells. The logic underlying this strategy is simple: if the aberrant biological state of cancer cells derives from and depends on malfunctioning signaling proteins, then inhibiting or eliminating such proteins from a cell's circuitry should result in a cytostatic or cytotoxic response in these cells. Such responses should, in turn, halt further tumor progression or, better yet, cause a regression of tumors.

Two other factors have furthered this thinking. First, knowledge gleaned over the past four decades about the machinery that governs normal and neoplastic cells has provided us with a wealth of potential molecular targets. Second, because the molecular targets function differently in normal and neoplastic cells, targeting these molecules should yield substantial therapeutic indices, that is, selective killing of cancer cells versus normal cells and potentially reduced side-effect toxicities for cancer patients under treatment.

This agenda, attractive as it may be, is constrained by certain functional realities. Drugs—usually low-molecular weight organic compounds—generally inhibit rather than enhance biochemical functions. This simple fact drastically narrows the options for the development of anti-cancer drugs. As we saw in Chapter 7, the protein products of tumor suppressor genes—the so-called gatekeepers—contribute to cancer development through their absence and attempts at developing low–molecular-weight compounds to replace or replicate these missing functions are impractical at present. The few successes here represent relatively minor victories. For example, certain compounds can restore some p53 function by shifting mutant forms of the p53 protein from their functionally defective stereochemical configurations back into a wild-type configuration.

Precisely the same arguments apply to the proteins responsible for maintaining the cellular genome—the caretakers (see Chapter 12). Once again, their functions, often missing from cancer cells, cannot be restored by even the most complex drug molecules. And even if they were, little utility would derive from such successes. After all, if the progression of a tumor has been driven by defective DNA repair and resulting accumulation of mutant alleles, restoration of the missing DNA repair function will have no effect on the many mutant sequences that have already accumulated in the genomes of its constituent cancer cells.

Once gatekeepers and caretakers are removed from consideration, such logic leaves oncoproteins—hyperactive forms of normal cellular growth- and survival-promoting proteins—as the most attractive targets for the development of anti-cancer therapies. These are molecules that, in principle, can be inhibited by drugs, resulting in reduction of their activity and, with luck, collapse of the neoplastic growth program. In fact, the signal-transducing proteins immediately downstream of hyperactive oncoproteins are also attractive targets, because most of these are also important positive effectors of signaling (**Figure 17.12**).



A diagram shows a receptor and the signalling pathway connected to it along with the different mechanisms of inhibition. The pathway leads to cell cycle progression, survival, and proliferation. The inhibitors include anti E r b B 2 receptor Mo Abs, JAK inhibitors, S r c inhibitors, anti HER 1 2 and 4 tyrosine

kinase inhibitors, P D K 1 inhibitors, RAS inhibitors, m TOR inhibitors, A k t inhibitors, P I 3 inhibitors, RAF inhibitors, B T K inhibitors, M E K inhibitors, and C D K inhibitors.

Figure 17.12 Inhibition of tumor growth by targeting downstream signaling elements As indicated in this diagram, signaling from receptors such as the EGF (HER1) and HER2/Neu receptors can be blocked in a number of ways. The ectodomains of the receptors can be targeted by monoclonal antibodies such as Herceptin. Moreover, the tyrosine kinase (TK) signal-emitting domains of these receptors can be targeted by a variety of low–molecular-weight drug compounds. In addition, several drugs have been developed that target proteins functioning as components of downstream signaling pathways, including those that inhibit Ras, both Raf and MEK (through inhibition of their serine/threonine kinase catalytic functions), mTOR (through inhibition of the formation of functional signaling complexes between mTOR and associated partner proteins), and cyclin D1 (through the inhibition of cyclin-dependent kinases). (Courtesy of J. Baselga.)

Certain genetic considerations may further narrow the range of molecules that are attractive targets for anti-tumor drug development. Earlier, we learned that as cancer progresses, cell populations acquire a succession of genetic and thus biochemical alterations that ultimately lead these cells to the neoplastic growth state (see Chapter 11). This scenario raises a provocative question: Do the changes that were responsible for the *early* steps of multi-step tumor progression continue to play critical roles far *later*, when the full-blown malignant phenotype has finally been acquired? For example, if the initial step in the development of a tumor involved the formation of a *ras* oncogene, are the continued actions of this oncogene still required later by the highly malignant descendant cells? Or have some of the changes occurring later during tumor progression rendered the continued functions of a Ras oncoprotein unnecessary?

Take the case of pancreatic carcinomas, in which the K-*ras* oncogene is found in the great majority (~90%) of tumors. The acquisition of this oncogene occurs relatively early in tumor progression, because mutant K-*ras* oncogenes are often found in pancreatic intraepithelial neoplasias (PanINs; see **Supplementary Sidebar 11.3**), the benign precursors of frank carcinomas. Do some of the subsequently acquired changes in, for example, the *Smad4/DPC4* and $p16^{INK4A}$/*CDKN2A* genes make the K-Ras4B oncoprotein superfluous? If so, drugs designed to block K-Ras signaling will never prove useful for treating this class of cancers.

Here, we can take some encouragement from a number of mouse models of cancer development (**Table 17.6**). The oncogene responsible for initiating tumor progression in tumor-prone transgenic mice can be shut off experimentally many weeks later in the tumors that eventually form. Such experiments have exploited the H-*ras* oncogene to create melanomas, the K-*ras* oncogene to induce lung adenocarcinomas, the *bcr-abl*

oncogene to create leukemias, and the *myc* oncogene to make islet cell tumors of the pancreas as well as leukemias and lymphomas. In all of these cases, the tumor cells that arise continue to be dependent on the initiating oncogenes, as indicated by the regression of these tumors once expression of the initiating oncogenes is shut down experimentally. The behavior of certain human tumor cells also indicates the continuing essential contributions of initiating genetic elements to cancer cell survival and tumor growth (**Sidebar 17.6**).

Table 17.6 Effects of shutting down expression of an initiating oncogenic transgene in tumor-prone mice

Transgenic oncogene	**Response of tumors**
Permanent regression after shutdown of transgene	
H-*ras*	melanoma regressed
K-*ras*	lung adenocarcinoma regressed
bcr-abl	B-cell leukemia regressed
myc	T-cell lymphoma, acute myelogenous leukemia, and epidermal, mammary, and islet cell carcinomas regressed
fgf-7	lung epithelial hyperplasia regressed
SV40 large T	salivary gland hyperplasia regressed if transgene expressed < 4 months
wnt1	mammary adenocarcinoma regressed
Persistence or relapse after shutdown of transgene	

Transgenic oncogene	Response of tumors
SV40 large T	salivary gland hyperplasia relapsed if transgene expressed > 4 months
neu	mammary adenocarcinoma regressed and then relapsed
myc	mammary adenocarcinoma relapsed in presence of K-*ras* oncogene
wnt1	mammary adenocarcinoma relapsed in absence of p53 function

Sidebar 17.6 HeLa cells provide the most dramatic example of the ongoing importance of initiating genetic lesions

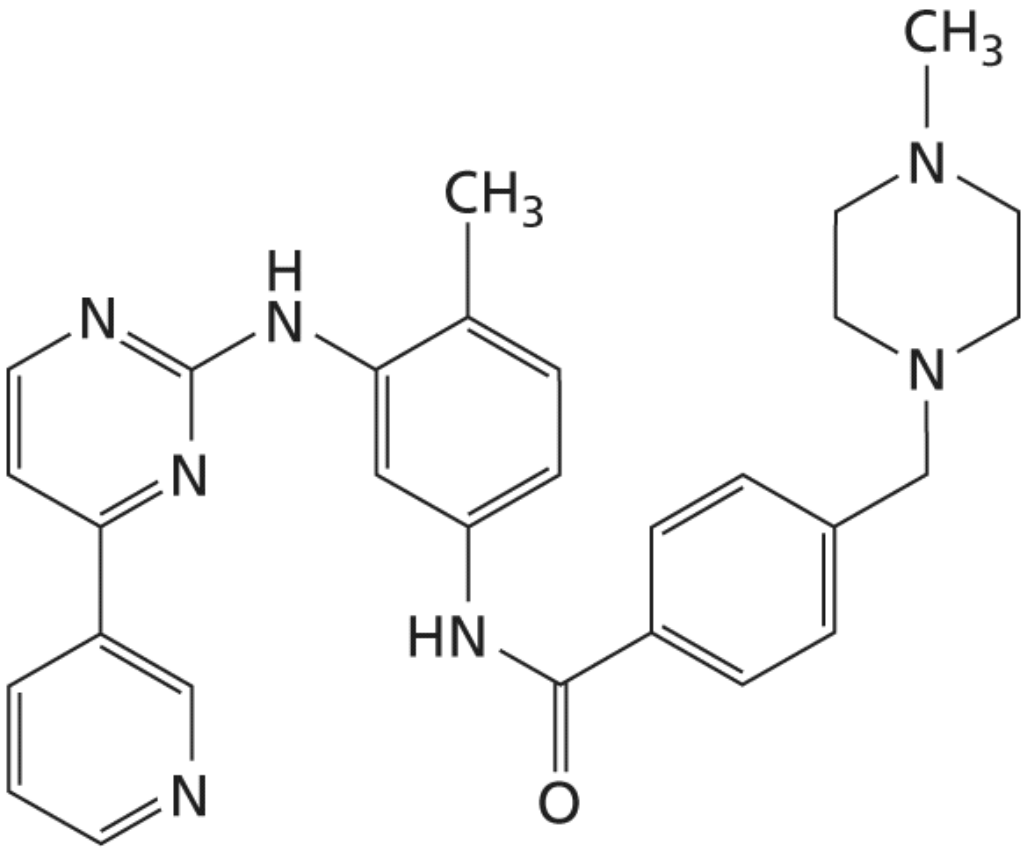
Arguably the most extreme example of the continued influence of initiating genetic lesions is provided by the behavior of the cells of the human HeLa cervical cancer cell line. Recall that these cells were derived in 1951 from a highly aggressive cervical carcinoma (see **Supplementary Sidebar 13.3**) and, like almost all (>99.7%) cervical carcinomas, the initiation of this tumor is traceable to a human papillomavirus (HPV) infection, in this case HPV type 18 and its two encoded oncoproteins, E6 and E7. Half a century later, during which time cultured HeLa cells passed through many thousands of growth-and-division cycles, genetic strategies were used to shut down the HPV18 oncogenes being expressed in these cells. The shutdown of E7 expression led to reactivation of pRb function and cell senescence, and shutdown of E6 led to the reappearance of p53 and subsequent senescence or apoptosis in these cells. Therefore, in the case of HeLa cells, the initiating genetic change (acquisition of an HPV genome) continued to be absolutely essential for the maintenance of cancer cell proliferation and viability thousands of cell generations later.

This continued dependence on an oncogene, often an initiating oncogene, has been termed oncogene addiction to indicate the irreplaceable role that such a gene plays in the ongoing viability of the cancer cell and growth of the tumor. We will encounter this physiological state again later in this chapter.

The biochemical subtleties of the oncoproteins that have been chosen as attractive targets for drug intervention, as described above, further complicate attempts at developing novel anti-cancer drugs. These drugs are, almost invariably, low–molecular-weight organic compounds, because (1) in general, such molecules are produced far more readily by synthetic organic chemistry than molecules of higher molecular weight; and (2) small molecules are more likely to penetrate into the interstices of a tumor, thereby exerting therapeutic effects on all of its component cells.

These potential molecular targets fall into two major categories—those that are druggable and those that are not. “Druggability” implies that the target molecule has a structure that should make it vulnerable to attack and inhibition by low–molecular-weight compounds. Stated differently, druggable cellular targets—invariably proteins—must have domains within their structures that are capable of strong and specific interactions with small drug molecules.

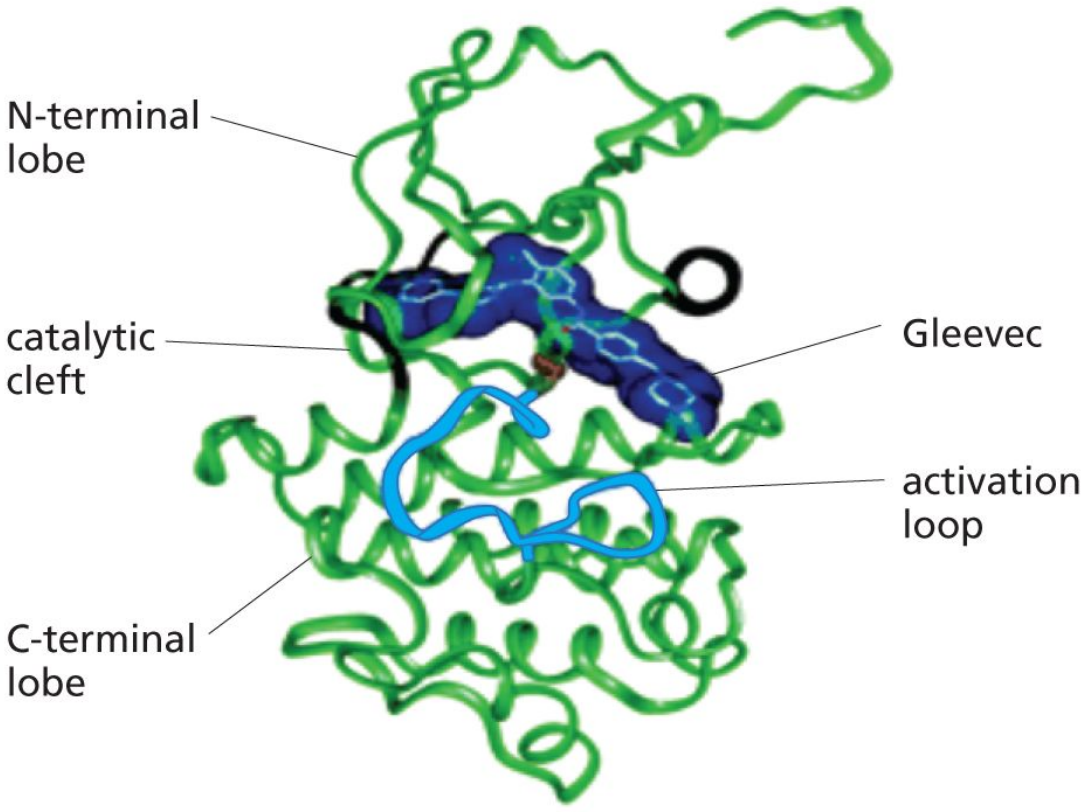
A protein is considered druggable if it has a cavity, usually a well-defined catalytic cleft. Such clefts are attractive for drug developers, because they usually can bind small organic molecules in a highly specific manner. In particular, these cavities often make it possible for a low–molecular-weight compound to form noncovalent bonds simultaneously with multiple amino acid residues lining their walls (**Figure 17.13**; see also Figure 17.46). These multiple independent contacts enable a drug molecule to bind the targeted protein with great specificity and avidity. Additionally, such binding has a high likelihood of perturbing protein function, because, in the case of catalytic clefts, the drug molecule occupies a functionally critical domain of the protein.



Gleevec®
(imatinib mesylate)

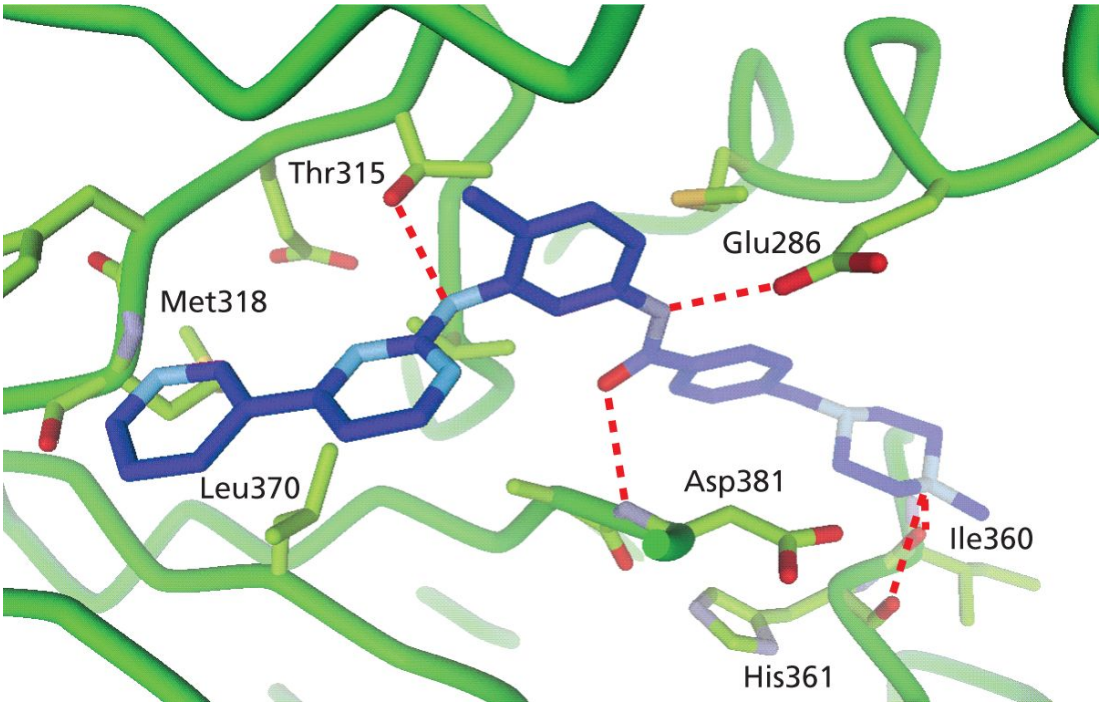
The molecular structure of Gleevec or imatinib mesylate.The structure contains five six membered ring structures that are linked by carbons and nitrogens. There is one carbonyl group in the middle of the structure.

(A)



A diagram shows a protein with a catalytic cleft between the N terminal lobe and the C terminal lobe. Gleevec is positioned within the catalytic cleft above the activation loop of the protein.

(B)



A magnified view of the position of Gleevec in the catalytic cleft. Gleevec hydrogen bonds with four amino acids in the protein which are T h r 315, G l u 286, A s p 381, and H i s 361.

(C)

Figure 17.13 Multiple contacts between drugs and their targets (A) The chemical structure of Gleevec, which was developed to inhibit the tyrosine kinase activity of the Bcr-Abl fusion protein active in chronic myelogenous leukemia (CML), was the result of optimizing the structure of a precursor compound to which certain side chains were added while others were removed in order to improve drug binding to the catalytic cleft of the Abl tyrosine kinase domain. (B) The catalytic cleft of the Abl kinase is found between its N- and C-terminal lobes, shown here as green ribbon structures. A space-filling model (with van der Waals radii) of a Gleevec molecule is shown in *dark blue*, and the "activation loop" of Abl, which normally blocks access to substrates by the catalytic cleft, is shown in *light blue*. (This activation loop swings out of the way when the kinase shifts into its active configuration.) (C) The avid and specific association of Gleevec (*blue*) with the catalytic cleft of Abl depends on the formation of multiple hydrogen bonds (*red dashed lines*), as well as weaker van der Waals interactions (*not shown*). These bonds increase the binding affinity of the drug for the protein; at the same time, they explain the specificity of association, because the various pairs of proton donors and acceptors, which participate as partners in hydrogen bond formation, must be precisely positioned in three-dimensional space. (A and

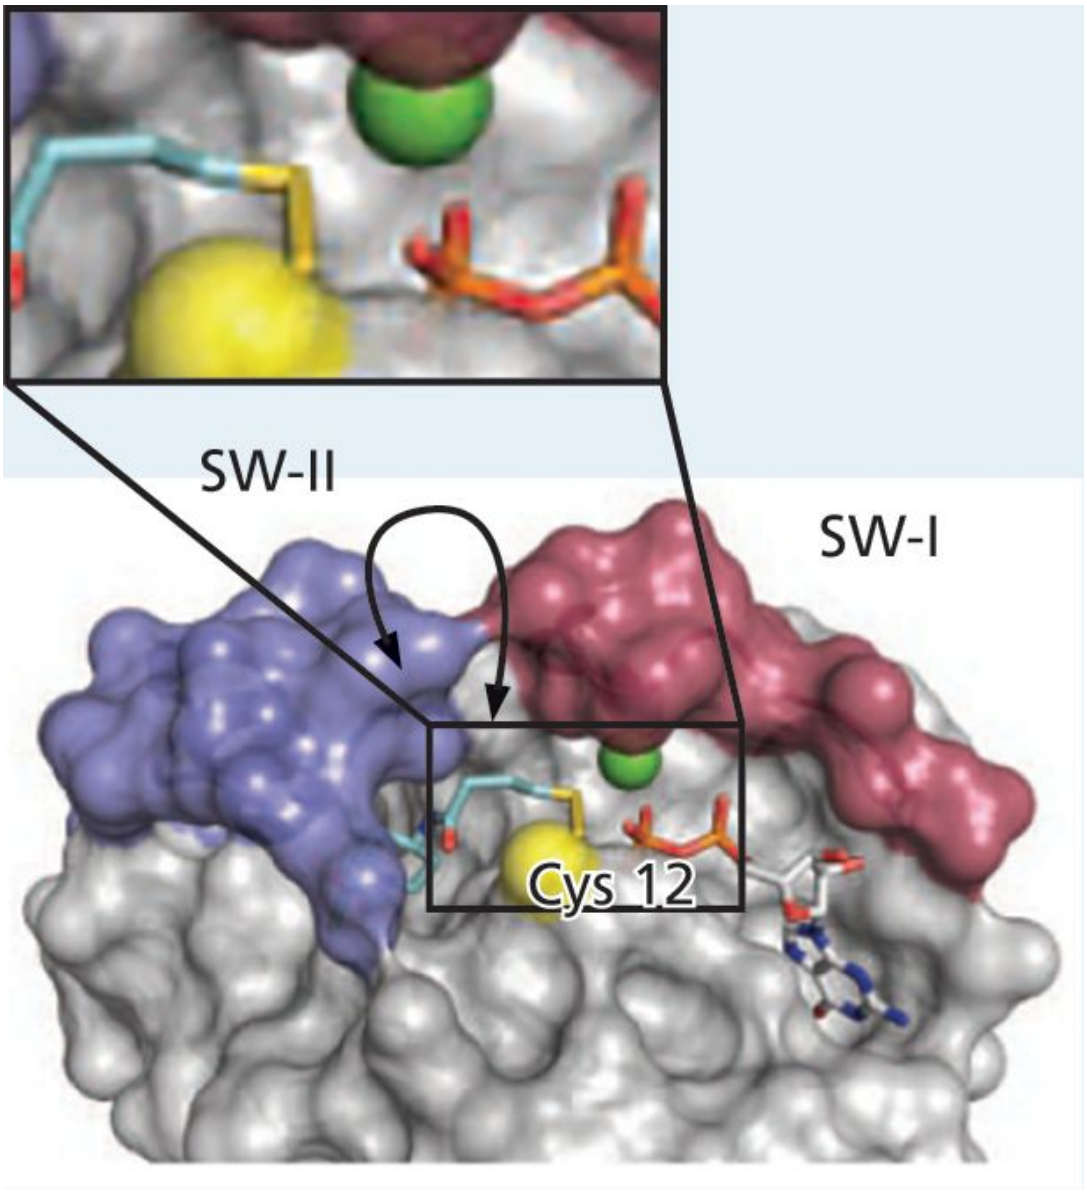
B, from B. Nagar et al., *Cancer Res*. 62:4236–4243, 2002. With permission from American Association for Cancer Research. C, courtesy of Novartis Pharmaceuticals.)

An equally important aspect of drug development is that pre-clinical evaluations of candidate drug molecules are greatly helped if the protein has a well-defined, measurable enzymatic function that underlies its oncogenic effect (**Sidebar 17.7**).

Sidebar 17.7 Targeting the Ras Oncoprotein

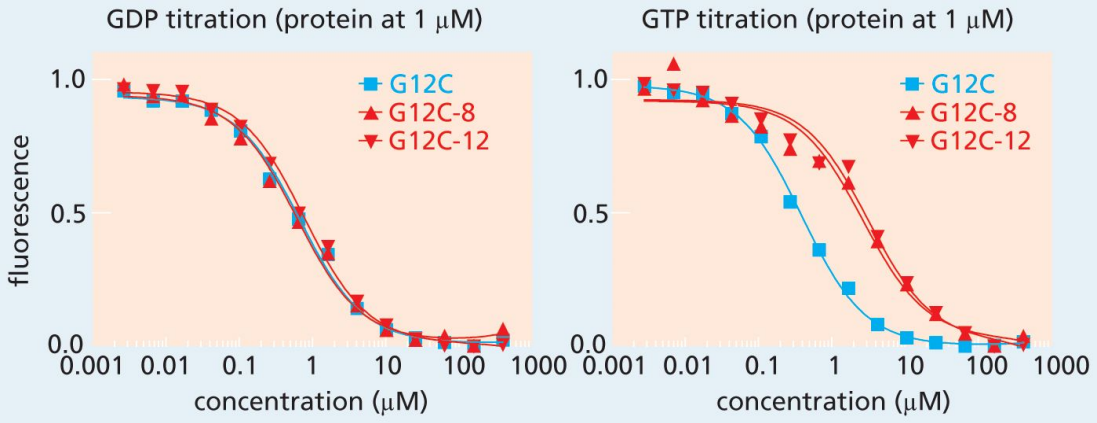
The presence of an identifiable catalytic function and apparent druggability does not, on its own, guarantee that an attractive target has been identified. Consider, for example, the case of the Ras oncoprotein, which has a clearly identifiable catalytic activity—its GTPase function. This enzymatic activity in Ras-expressing cells has never been the object of drug development because the Ras GTPase, as we learned in Section 5.10, functions as a *negative* regulator of Ras signaling. Its inhibition would only augment the already disastrous effects of the amino acid substitutions that create Ras oncoproteins in the first place. The same can be said of many tyrosine phosphatases, whose designated roles are to reverse the effects of growth-promoting tyrosine kinases (see Section 6.3), and, similarly, the activity of the PTEN phosphatase, which serves to counteract the actions of PI3K (see Figure 6.14).

Notably, although Ras has long been an undruggable target, recent work has provided a clear therapeutic strategy to target a specific allele-encoded variant of oncogenic Ras. The G12C mutation is found in non-small-cell lung carcinomas (NSCLCs) developed by current and former smokers, representing ~12% of all Ras mutations in these tumors. Small-molecule-tethering experiments identified a targetable pocket in GDP-bound but not GTP-bound form of this oncoprotein. Ras (G12C) occupies this GDP-bound form more frequently than do other Ras mutants and, like all other Ras proteins, requires guanine nucleotide exchange factors (GEFs; see Figure 6.25A) to be activated. Small drug molecules with a thiol group can bind covalently to the cysteine residue present in this mutant Ras oncoprotein and lock this protein in the GDP-bound inactive form (**Figure 17.14**). Consequently, first-in-class inhibitors of RASG12C have entered clinical trials in solid tumors that carry this mutation.



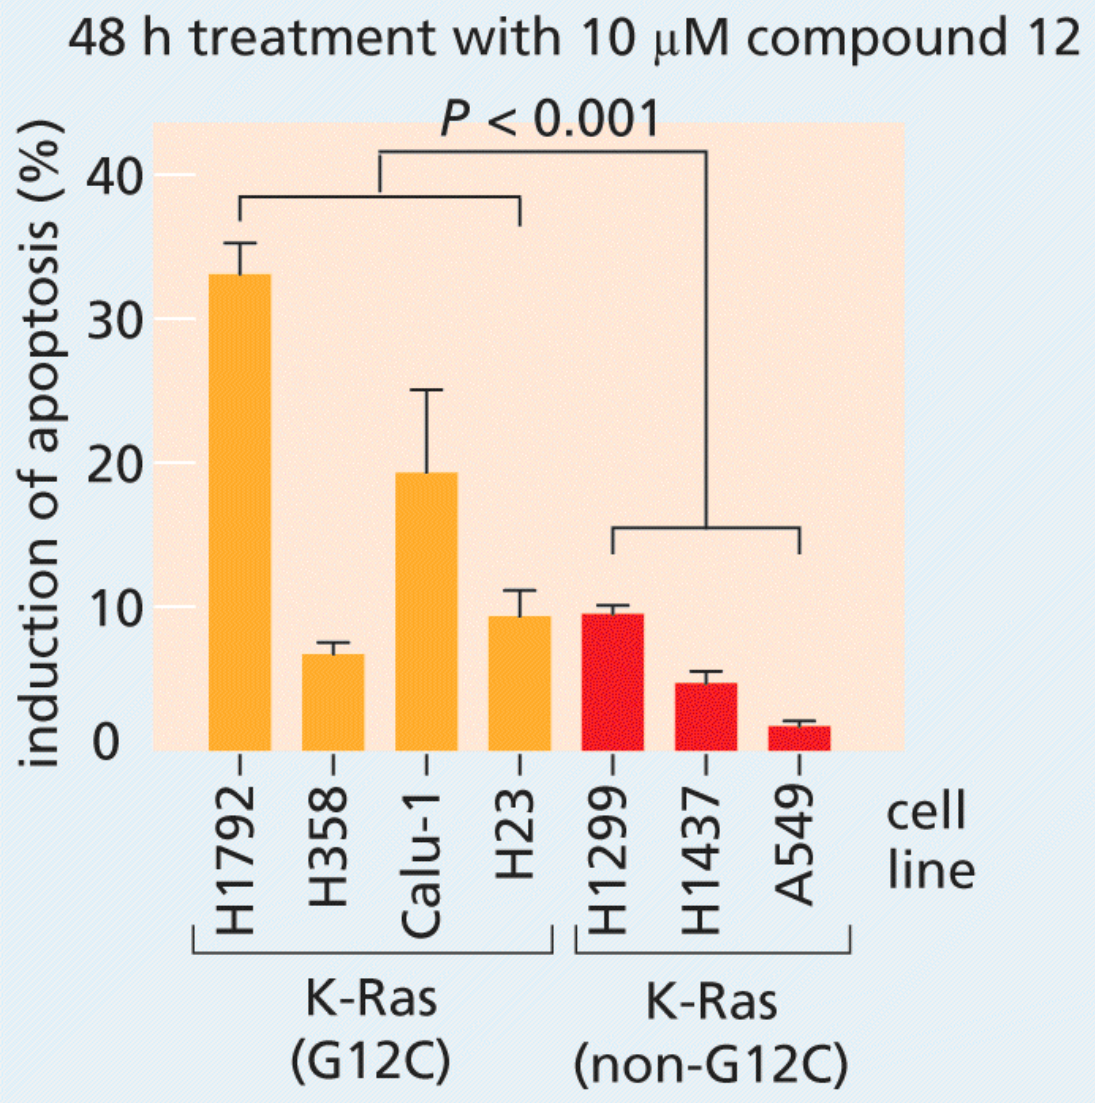
A space filling model of mutant K Ras with a molecule binding in a cleft below the S W 1 and S W 2 subunits. The molecule is interacting with C y s 12 at the base of the cleft.

(A)



Two graphs of G D P and G T P titration of proteins at 1 micromolar. Both graphs have concentration in micromolar on the x axis and fluorescence from 0 to 1 on the y axis. Three proteins are measured: G 12 C, G 12 C 8, and G 12 C 12. All curves have the same inverse S shape, starting near a fluorescence of 1 and ending near a fluorescence of 0. In the G D P titration graph, all three curves are close to each other where the steepest decrease in fluorescence occurs near a concentration of 1 micromolar. However, in the G T P titration graph, G 12 C 8 and G 12 C 12 are shifted to the right such that the steepest decrease occurs around a concentration of 8 micromolars.

(B)



A graph shows the percent induction of apoptosis after 48 hours of treatment with 10 micromolar compound 12 for different cell lines. Four cell lines have G 12 C K Ras and three cell lines have non C 12 C K Ras. These two groups have statistically different percent induction of apoptosis at the p is less than 0.001 level. In the G 12 C K Ras cell lines the percent induction of apoptosis ranges from 8 to 32. In the non G 12 C K Rad cell lines the percent induction of apoptosis is always less than 10.

(C)

Figure 17.14 Compounds that can specifically bind to oncogenic K-Ras (G12C) Certain small molecules compounds rely on the mutant cysteine residue present within mutant K-Ras (G12C; *yellow*) for binding and consequently do not interact with wild-type K-Ras. (A) Crystallographic studies of K-Ras (G12C)

show a new pocket that is beneath the effector binding switch-II region (SW-II, *purple*). Here, the small molecule inhibitor forms a disulfide bond with Cys12 of K-Ras (G12C) (shown in the blown-up image). (B) As described in Figure 6.8B, K-Ras exists in an inactive GDP-bound state and an active GTP-bound state. The graph shows GDP and GTP titration assays that measure the relative affinity of K-Ras (G12C) for GDP and GTP in the presence and absence of certain small molecule inhibitors. Binding of these compounds to K-Ras (G12C) shifts the relative nucleotide affinities of Ras to favor GDP over GTP, causing K-Ras (G12C) to accumulate in the inactive state. (C) A small molecule inhibitor of K-Ras (G12C) (here designated compound 12) preferentially induces cell death in tumor cell lines expressing K-Ras (G12C) vs. wild-type K-Ras. (A–C taken from J. M. Ostrem et al., *Nature* 503(7477):548–551, 2013. With permission from Nature.)

Proteins lacking such catalytic clefts are often dismissed as being “undruggable.” Transcription factors, for example, are widely thought (rightly or wrongly) to be undruggable, because they usually lack catalytic clefts and thus the much-sought drug-binding pockets. Hence transcription factor oncoproteins, such as Myc and Fos, are placed in the category of undruggable targets, whereas the many kinases involved in cancer formation are placed in the camp of druggable target molecules.

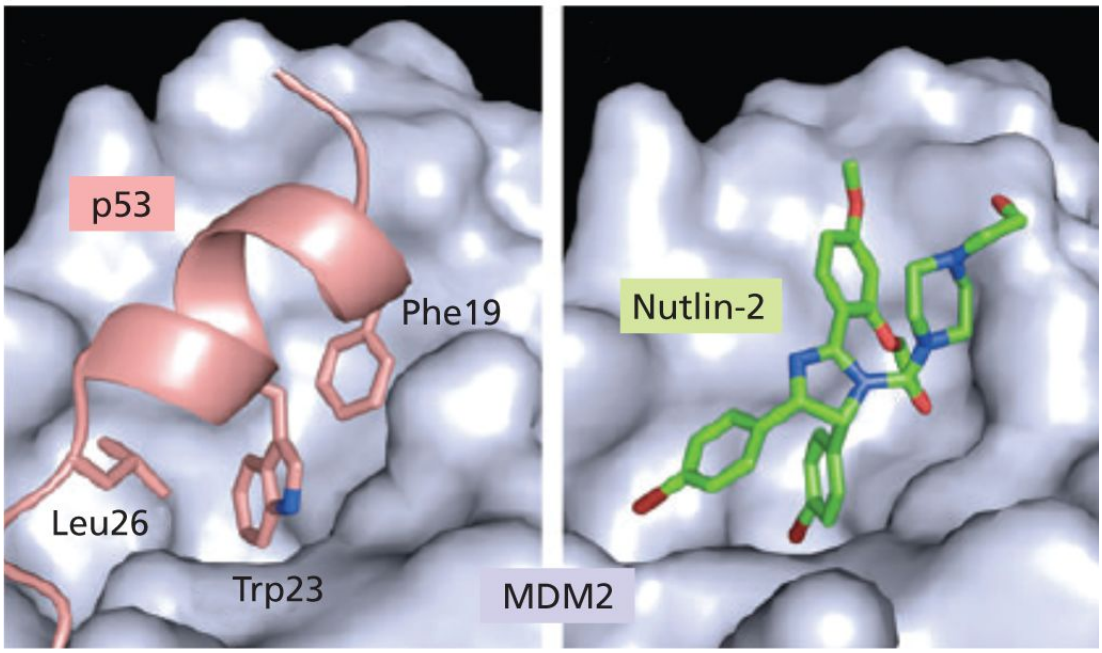
(The major exceptions to the lack of druggability of transcription factors are the nuclear hormone receptors, such as the estrogen and progesterone receptors. Because they have hormone-binding pockets, these receptor proteins are vulnerable to disruption by pseudo-ligands, such as tamoxifen, which bind and antagonize certain functions of the estrogen receptor.)

The difficulties in directly targeting transcription factors with small molecules have led to a diverse set of strategies to indirectly perturb transcription factor levels or activity. These include blocking transcription factor/co-factor interactions, disrupting transcription factor interaction with DNA or histones, or increasing the level of ubiquitylation and subsequent proteasome degradation of transcription factors. However, the impact of these approaches on cancer treatment remains largely unrealized.

The notion that molecular cavities provide attractive targets for drug development might also suggest that many types of protein–protein interactions represent druggable targets. After all, the confined space between two physically apposed proteins would seem likely to create a highly specific drug-binding pocket, and insertion of a drug into such a cavity might therefore destabilize or block the protein–protein interaction.

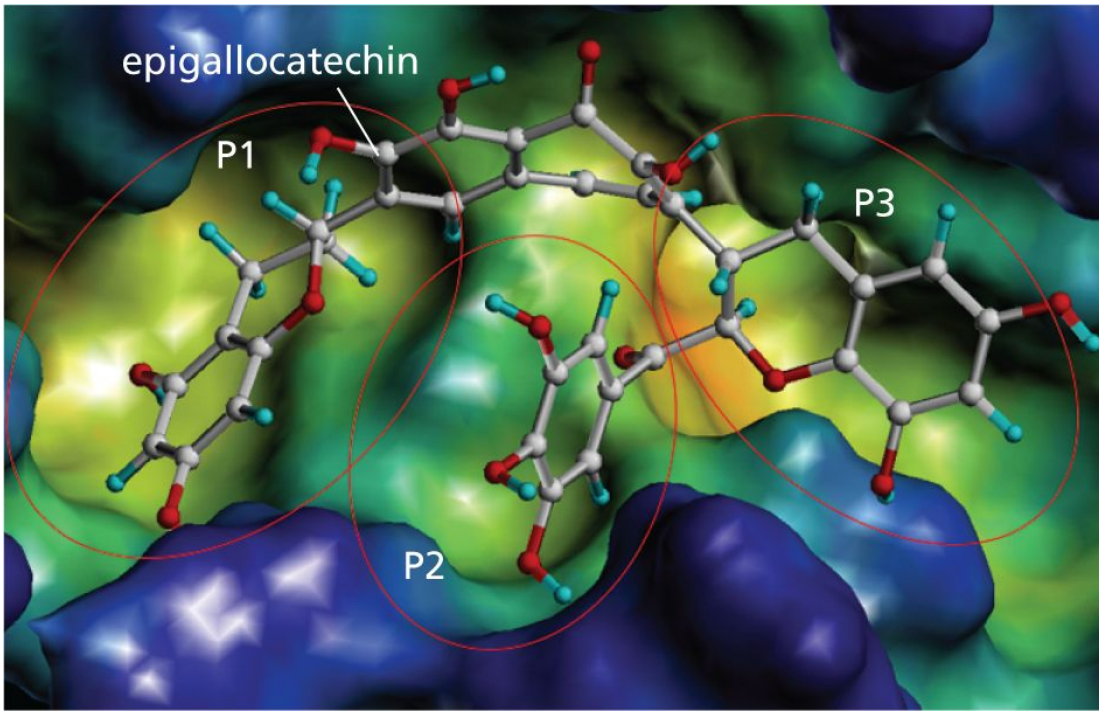
Unfortunately, most attempts at preventing these and other protein–protein associations through custom-made drug molecules have been unsuccessful. The numerous failures were rationalized as follows: the association of two proteins with one another involves multiple points of binding between their interacting faces. These points of contact extend over wide molecular domains that greatly exceed the dimensions of drug molecules, which typically have a rather low molecular weight (generally <600). Consequently, only a small fraction of the contact points between two associating proteins can be blocked by any single drug molecule, and the association as a whole remains essentially unperturbed.

An exception to this widely accepted lore was announced in late 2003, when a low–molecular-weight compound (termed *nutlin*) that inhibits formation of the Mdm2–p53 complex (see Section 9.8) was described (**Figure 17.15A**). This development meant that, in principle, the absence of functionally adequate levels of p53 protein observed in many types of human tumors—often resulting from loss of $p14^{ARF}$ expression or overexpression of Mdm2—could be reversed by drug treatment.



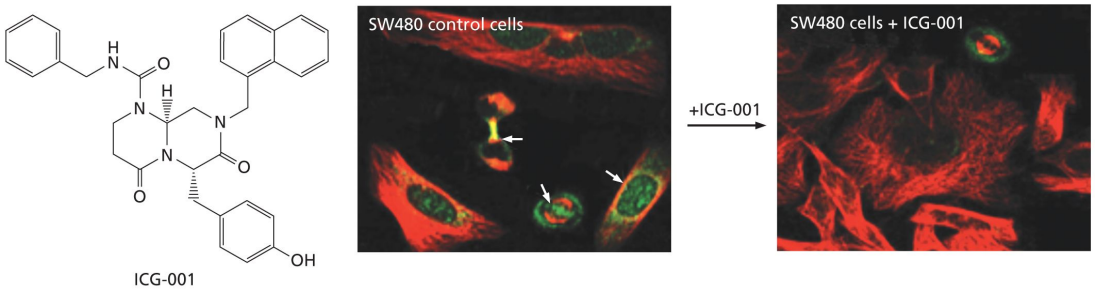
Two 3 D models show p 53 and Nutlin 2 binding within the same cleft in M D M 2. They interact with Leucine 26, Tryptophan 23, and Phenylalanine 19.

(A)



A 3 D model shows epigallocatechin binding to B c l X. Three regions of the molecule are circled and labeled P1, P2, and P3. These regions interact strongly with the protein.

(B)



The molecular structure of I C G 001 and two fluorescence microscopy images of cells with and without I C G 001. The structure consists of a two six membered ring complex at the center where each ring has two nitrogen atoms. There are side chains that branch off of this that have multiple benzene rings. The S W 480 control cells have green staining in the center. However, the S W 480 cells with I C G 001 have no green staining.

(C)

Figure 17.15 Inhibitors of protein–protein interactions (A) A search for compounds that inhibit Mdm2–p53 binding resulted in the discovery of Nutlin-2, which associates with the p53-binding pocket of Mdm2, whose surface is shown here. The usual interaction of the transactivation domain of p53 (*pink*; see Figure 9.6) with a hydrophobic cleft near the N-terminal domain of MDM2 (*gray, left*) (see Figure 9.11A) is mimicked by the Nutlin-2 molecule (*stick figure*) binding the same hydrophobic cleft of MDM2 (*right*). Nutlin-2 and closely related compounds prevent Mdm2-mediated p53 degradation and thereby act to trigger apoptosis in certain cancer cells, achieving both effects at low micromolar concentrations. (B) Some of the constituents of tea leaves induce apoptosis in tumor cells at very low concentrations. Epigallocatechin gallate (EGCG; *stick figure*) extracted from green tea binds the important anti-apoptotic protein Bcl-X_L with an inhibitory constant (K_i) of 490 nM and Bcl-2 with a K_i of 335 nM. (K_i values reflect the concentrations at which 50% of the activity of these proteins is inhibited; values in the submicromolar range are indicative of high potency.) A combination of three technologies—nuclear magnetic resonance (NMR) binding assays, fluorescence polarization assays, and computational docking—was used to derive this image, which shows the docking of EGCG in three adjacent hydrophobic pockets of Bcl-X_L *(yellow* and *green)*, whose molecular surfaces are labeled P1, P2, and P3 here. These pockets together constitute a hydrophobic domain that Bcl-X_L, which is overexpressed in many cancer cells, uses to bind and neutralize pro-apoptotic BH3-only proteins (see Figures 9.26 and 9.28 and 17.27. (C) The small molecule ICG-001 *(left)* inhibits the association of the β-catenin–Tcf/Lef complex with the transcriptional co-activator CBP, a histone acetyltransferase (see Section 1.8). The transcription factor complex is responsible for inducing, among other genes, expression of the gene encoding survivin, a key inhibitor of apoptosis (IAP; see Section 9.15). As seen here, expression of survivin (*green, yellow immunofluorescence, center*) that is normally present in SW480 human colon carcinoma cells (*arrows*) is strongly reduced by the presence of ICG-001 (*right*)*;* tubulin (*red*) is used in both cases as a counterstain. The concentration of ICG-001 used in this experiment causes an approximately sixfold reduction in the activity of the survivin gene promoter (not shown). Clinical trials of ICG-001 and derivatives are ongoing. (A, from A.C. Joerger and A.R. Fersht, *Annu. Rev. Biochem*. 77:557–582, 2008. With permission from Annual Reviews. B, from M. Leone et al., *Cancer Res*. 63:8118–8121, 2003. With permission from American Association for Cancer Research. C, left, from K.H. Emami et al., *Proc. Natl. Acad. Sci. USA* 101:12682–12687, 2004; with permission from National Academy of Sciences, U.S.A.; right, from H. Ma et al., *Oncogene* 24:3619–3631, 2005. With permission from Nature.)

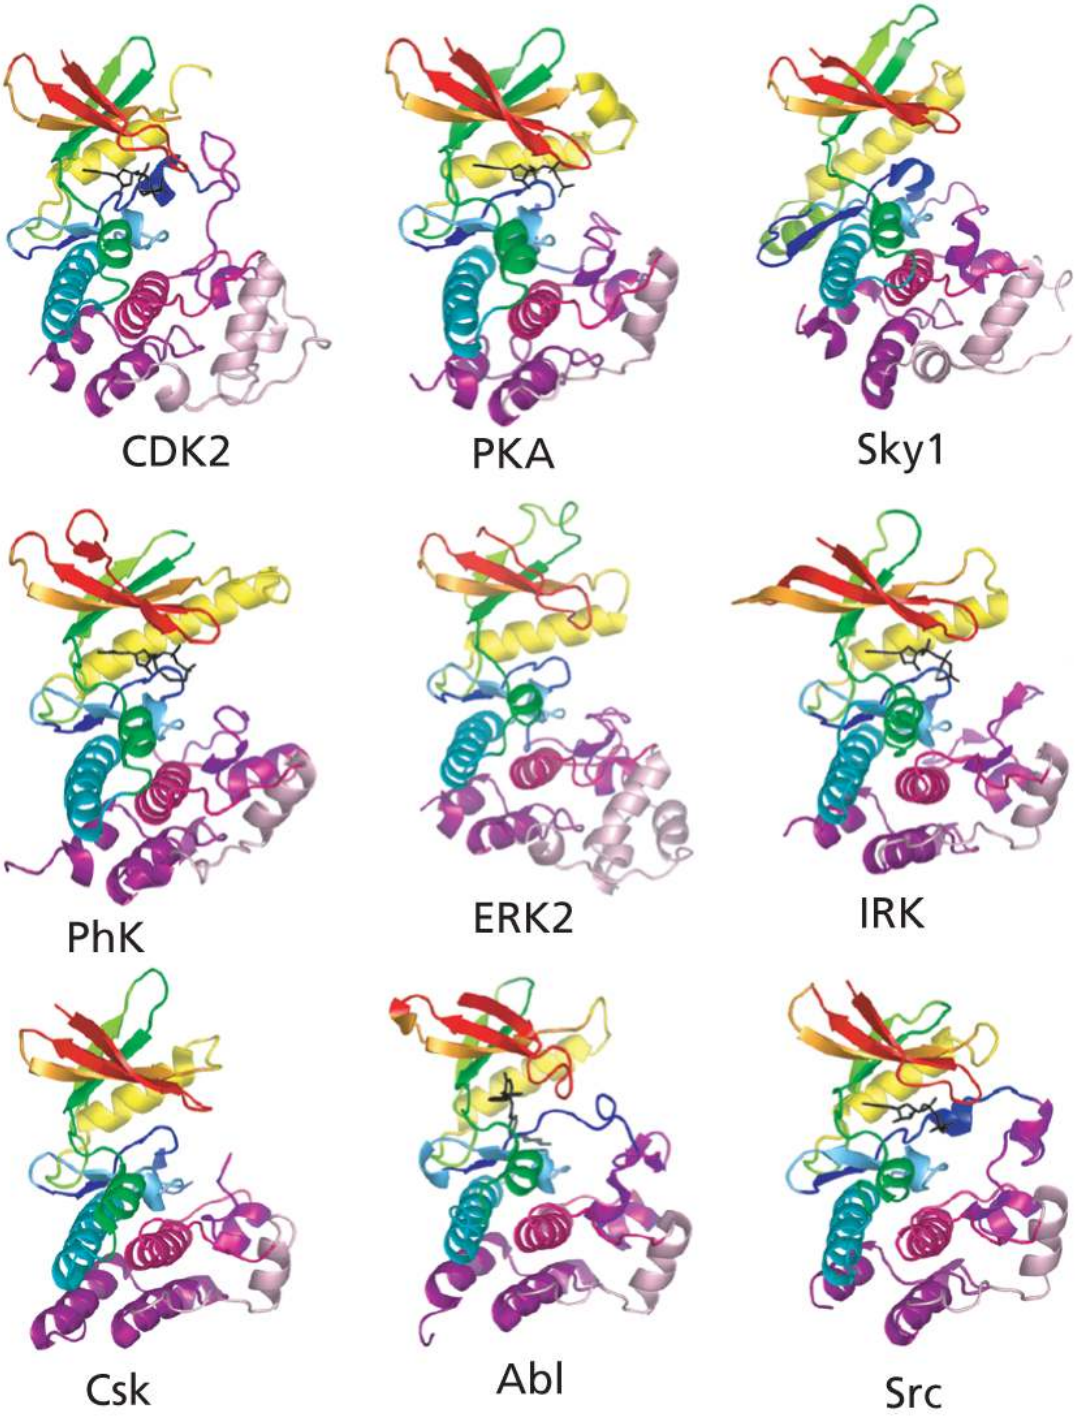
Subsequently, naturally occurring compounds isolated from green and black tea were found to block the binding and neutralization of pro-apoptotic BH3 proteins by the anti-apoptotic Bcl-2 and Bcl-X_L proteins, doing so at relatively low concentrations (see Figures 9.25C and 17.15B). As described in detail in Section 17.12, a synthetic inhibitor of the Bcl-2, Bcl-X_L, and Bcl-w proteins was generated that associates with these anti-apoptotic proteins with a binding affinity of approximately 1 nM—more than two orders-of-magnitude more avid than the tea compound. An additional compound, ICG-001, identified through high-throughput screening (HTS; **Supplementary Sidebar 17.6**), was found to be capable of inhibiting the association of β-catenin with CBP (cyclic AMP response element–binding protein), a widely acting transcriptional co-activator that works in the cell nucleus with β-catenin to induce expression of key genes, including the gene encoding survivin (see Table 9.4), an important anti-apoptotic IAP protein (see Figure 17.15C), as well as cyclin D1. Both ICG-001 and a 20-fold more potent derivative, termed PRI-724, have entered into clinical trials for treatment of leukemias and carcinomas of the colon and pancreas. Other obvious candidates for such inhibition were the several types of cyclin–Cdk pairs, whose actions drive the proliferation of all cancer cells (see Figure 8.10).

In the years that followed these pioneering efforts, successes have been reported in targeting an increasing number of other protein–protein interactions. Included among these are the interactions between Sos and Ras (see Sections 6.2 and 6.4); the ligand–receptor interactions between VEGF and PDGF and their respective receptors (see Section 5.6); and interactions between bromodomain-containing proteins with histones (see Section 1.8), VHL with HIF1α, and MLL with Menin (see Table 7.1).

These successes notwithstanding, kinases still reign supreme among the classes of cellular molecules that are attractive, druggable targets for anti-cancer therapy. As we have seen in Chapters 5 and 6, many of these kinases function as oncoproteins that act to drive neoplastic proliferation and, at the same time, are enzymes possessing well-defined catalytic clefts. Recall that at least 518 distinct kinase-encoding genes have been enumerated in the human genome, of which 90 encode tyrosine kinases (**Supplementary Sidebar 17.7**), which are major players in many kinds of human cancer.

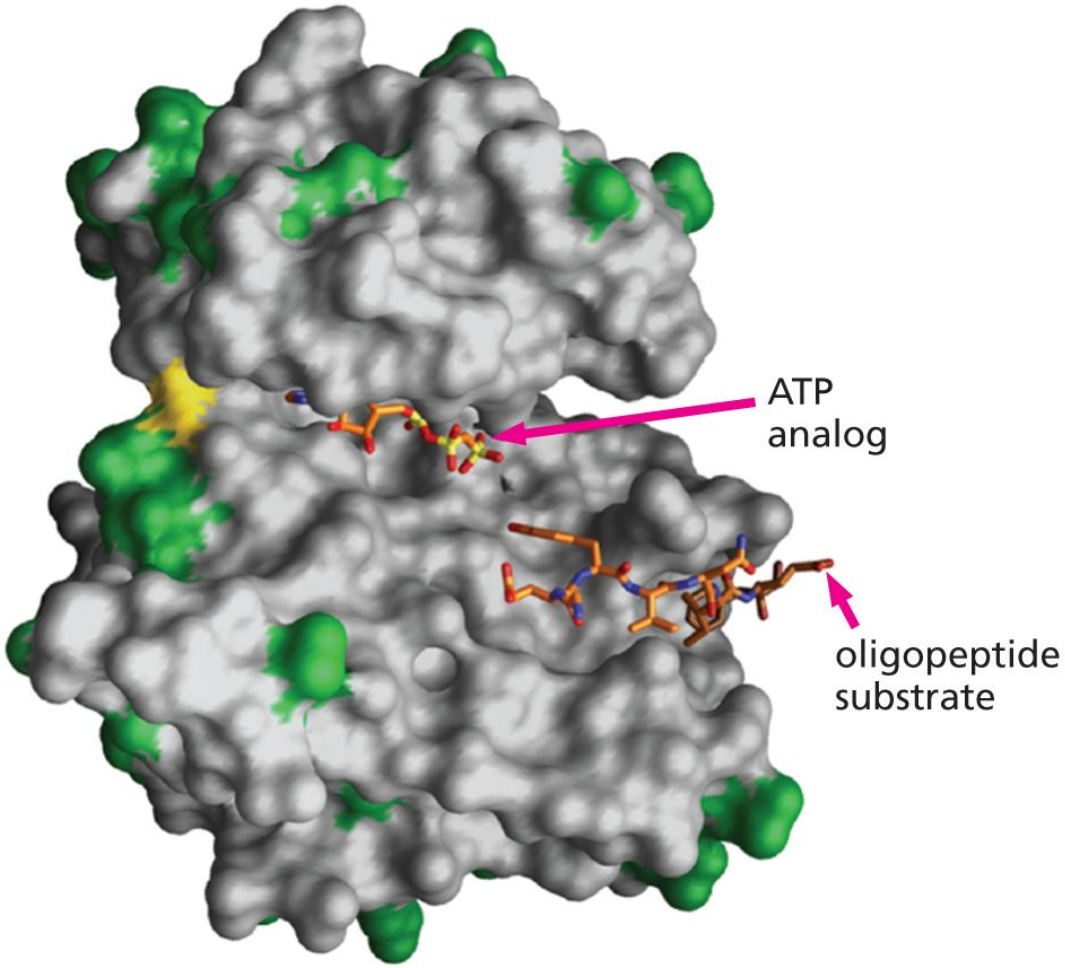
For some cancer researchers, this multiplicity of potentially druggable cancer targets represents an embarrassment of riches. However, for pharmaceutical chemists, numbers like these create a nightmare. Because almost all protein kinases are evolutionarily related (see **Supplementary Sidebar 17.7**), their catalytic clefts are structurally quite similar (**Figure 17.16A**). The similarity is even more striking among the clefts of the more closely related tyrosine kinases (Figure 17.16B) that are involved in cancer pathogenesis. How can one possibly develop agents that specifically affect

the actions of certain cancer-associated kinases, while leaving untouched the kinases required for normal cell proliferation and survival? Rational drug design and high-throughput screening, both described below, attempt to address these issues.



A series of ribbon diagrams show the structures of nine kinases. They include C D K 2, P K A, Sky 1, P h K, E R K 2, I R K, C s k, A b l, and S r c. All the

structures look very similar with multiple domains but slightly different conformations.
(A)



A 3 D model shows a protein that is mostly gray with a few protrusions on the outer edges shaded green. In the central cleft, an A T P analog is bound. The structure of an oligopeptide substrate is also shown.

(B)

Figure 17.16 Similar structures of kinases (A) The difficulty of producing a specific kinase inhibitor is suggested by the striking similarities in structure of a variety of serine/threonine and tyrosine kinases. Depicted here as ribbon diagrams are the kinase domains of five serine/threonine kinases: CDK2 (see Chapter 8), PKA (cyclic AMP-regulated protein kinase A), Sky1 (SR-protein–specific kinase

of budding yeast, a serine kinase involved in yeast nuclear RNA processing), PhK (phosphorylase kinase involved in glycogen metabolism), and ERK2 (extracellular-regulated kinase of the MAPK cascade; see Section 6.5); as well as four tyrosine kinase (TK) domains: IRK (insulin receptor kinase), Csk (C-terminal Src kinase), Abl (see Figure 17.13), and Src (see Section 5.2). In all cases, the catalytic clefts of these kinases are sandwiched between the two major lobes (N- and C-terminal, above and below, respectively) of these proteins. (B) An extreme example of the structural similarities between related kinases is illustrated by this surface diagram comparing the catalytic clefts and adjacent amino acid residues of the tyrosine kinase domains of the insulin receptor (IR; see the IRK of panel A) and the insulin-like growth factor receptor (IGF-1R). Identical amino acid residues are in *gray* and dissimilar ones are in *green*. These structures show how very similar the catalytic regions of the two TK domains are and it explains why it was difficult to find inhibitors of one tyrosine kinase receptor that do not affect the other. A threonine in the peptide linking the two lobes of the kinases is shown in *yellow*, and stick figures (*multicolor*) of an ATP analog and an oligopeptide substrate (*right*) are also shown. Almost all TK antagonist drugs bind in the ATP-binding sites of the kinases that they inhibit. (A, courtesy of N.M. Haste and S.S. Taylor. B, from S. Favelyukis et al., *Nat. Struct. Biol*. 8:1058–1063, 2001. With permission from Nature.)

OceanofPDF.com

Glossary

oncogene addiction
: (1) The physiological state of a cancer cell in which it continues to be dependent for its proliferation or survival on the ongoing function of a certain oncogene, usually a mutant oncogene, often long after the oncogene has been acquired during the course of multi-step tumorigenesis. (2) More generally, ongoing dependence on any type of previously acquired genetic or epigenetic alteration.

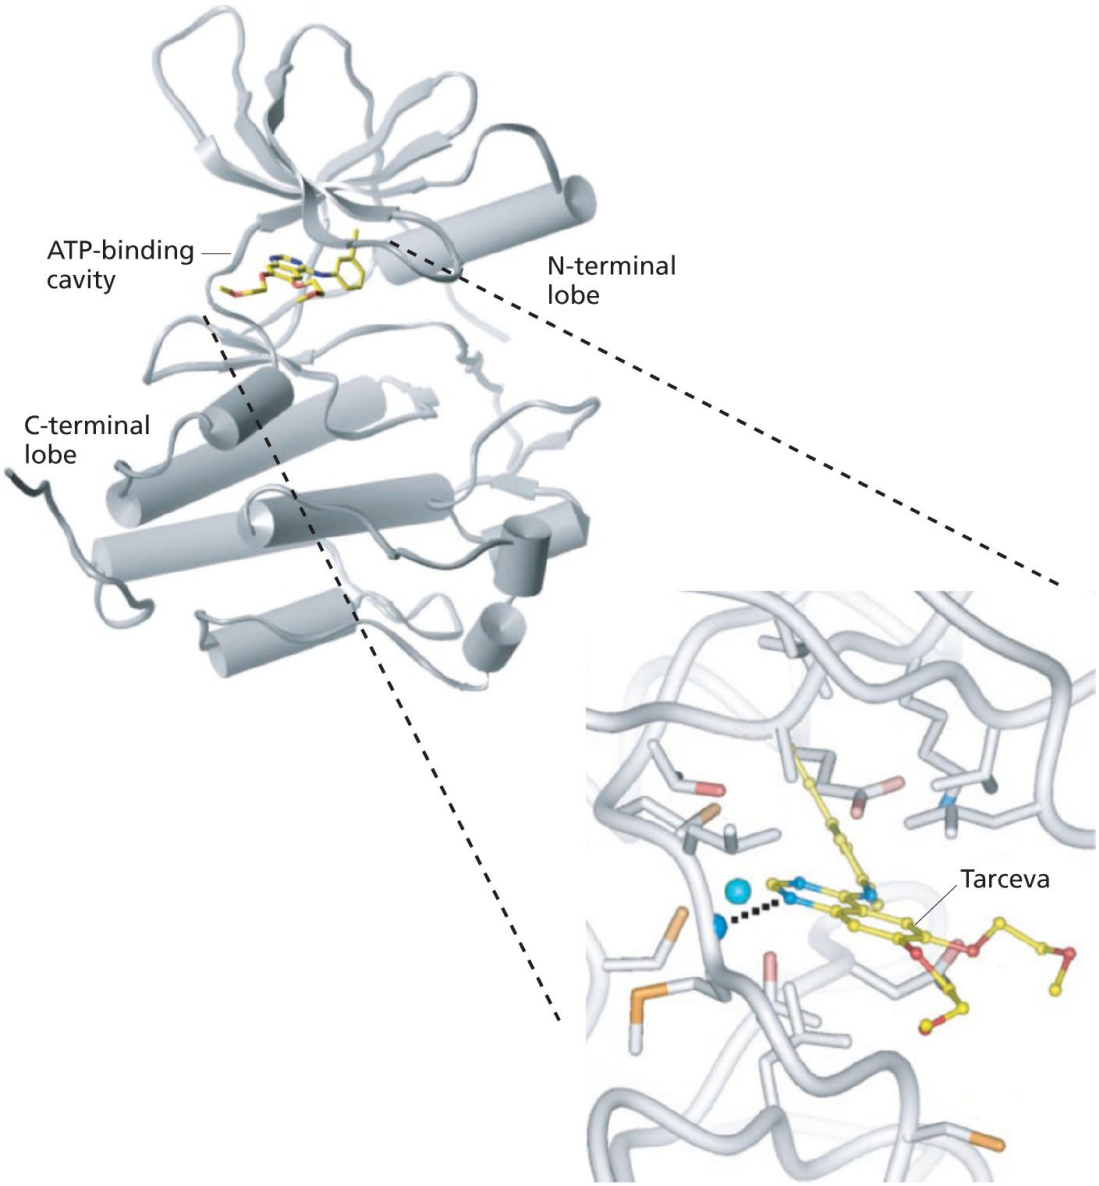
druggable
: Referring to a molecular species, such as a protein, that has the structural and functional properties suggesting that low–molecular-weight therapeutic drug compounds can be developed that specifically interact with and perturb its functioning; the structural properties include, most prominently, a drug-binding pocket that should permit high-affinity, multivalent associations between a drug molecule and the targeted protein.

therapeutic index
: (pl., **indices**) The ratio of the concentration of a drug that elicits an unacceptable level of toxicity compared with the concentration of the drug that elicits a desirable therapeutic response.

OceanofPDF.com

17.6 Pharmaceutical chemists can generate and explore the biochemical properties of a wide array of potential drugs

The ideology of “rational drug design,” as it is often called, embraces the notions that (1) drugs should be targeted against specific proteins known to be malfunctioning within cells, thereby contributing in functionally critical ways to a disease state; (2) the candidacy of these proteins as attractive targets for therapeutic intervention should be determined by their predicted druggability; and (3) the detailed molecular structures of such target proteins should inform the design of the chemical structures of the drugs that are to be developed. More specifically, chemical species must be synthesized whose detailed three-dimensional structures (that is, whose stereochemistry) enable them to fit, in a key-in-lock fashion, into specific pockets or sites within the far larger proteins that they are supposed to attack and disable (**Figure 17.17**).



Two diagrams show Tarceva binding in the A T P binding cavity of the E G F receptor tyrosine kinase. The cavity is between the C terminal lobe and the N terminal lobe.

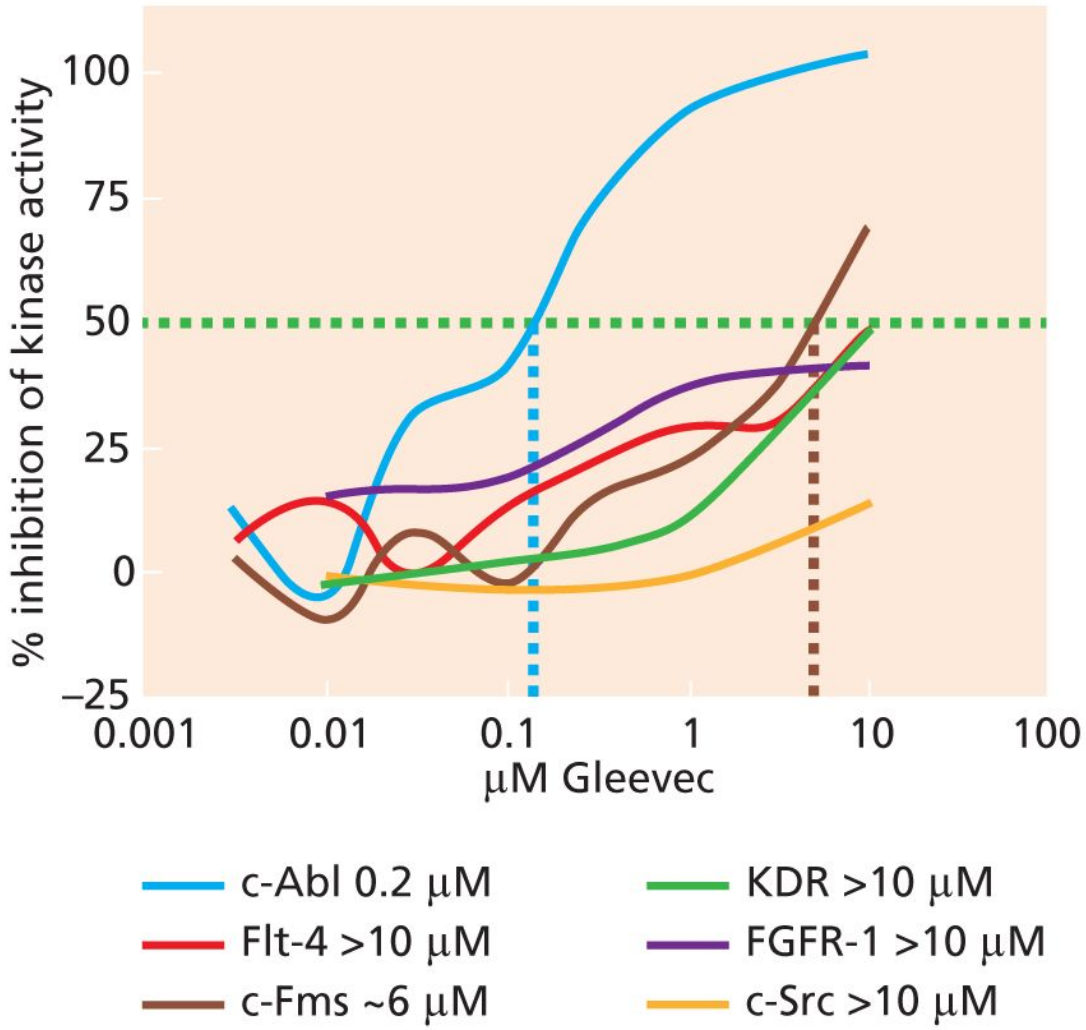
Figure 17.17 Tarceva and the inhibition of the EGF receptor kinase domain This model of the catalytic cleft of the EGF receptor tyrosine kinase (TK) domain, derived by X-ray crystallography, shows how the drug Tarceva fits snugly within the ATP-binding cavity of the cleft and in this way inhibits receptor signaling. The three-dimensional complementarity between drug and targeted protein is necessary for drug binding but not sufficient, because specific bonding, largely achieved through the formation of hydrogen bonds (*dashed line*), must occur between the drug molecule and amino acids lining the drug-binding pocket (see,

for example, Figure 17.13C). A water molecule (*light blue sphere*) that is hydrogen-bonded to the Tarceva molecule is also shown. (From J. Stamos, M.X. Sliwkowski and C. Eigenbrot, *J. Biol. Chem*. 277:46265–46272, 2002. © 2002 ASBMB. This article is available under a Creative Commons Attribution (CC BY 4.0) license.)

In principle, knowledge of the detailed structure of a potential drug-binding cavity in a targeted protein should allow a skilled synthetic organic chemist to design and synthesize a molecule that not only fits snugly into this cavity but also forms multiple noncovalent bonds with the amino acids lining its walls. According to this logic, the more bonds are formed, the higher the specificity and strength of binding of the candidate drug compound by the targeted protein. This purely theoretical route for designing a novel drug structure has led to some notable successes, including the development of the B-Raf inhibitor vemurafenib, the BCL-2 inhibitor venetoclax, and the CDK4 inhibitor ribociclib. However, these successes have been the exception, not the rule, for cancer drug development. For this reason, current drug discovery generally relies on more empirical ways of finding useful molecular structures, involving surveys of hundreds of thousands of compounds via high-throughput screening (HTS; **Supplementary Sidebar 17.8**).

Imagine that HTS has yielded a drug molecule that inhibits the activity of a targeted protein in living cells, doing so at an IC_{50} in the 10 to 100 micromolar range (that is, drug concentrations in this range are required for 50% inhibition of the activity of the targeted protein). Further development of this particular drug becomes unrealistic, given the massive amounts of this agent that would need to be delivered into a patient's body in order to achieve a desired therapeutic effect. The chemical properties of this molecular species may or may not allow derivatization (the synthesis of chemically modified derivatives of this compound) that yields a molecule with IC_{50} potency in the nanomolar concentration range, which is the prerequisite for drugs that are introduced into the clinic (see **Supplementary Sidebar 17.8**).

If such a drug is indeed successfully synthesized, the ensuing pre-clinical testing involves measurements of the drug's *relative* effects on its intended target compared with its off-target effects on other, similar proteins in the cell. The goal here is to determine whether the drug acts selectively by inhibiting the targeted protein at drug concentrations that are substantially below (10- to 100-fold) those affecting other similar proteins in the cell (**Figure 17.18**). (In truth, given the 20,000 or more distinct protein structures present in mammalian cells, these measurements do not preclude possible effects on structurally unrelated proteins that may, through happenstance, also be affected by an agent under development.)



A line graph shows the dose response curves of Gleevec with six different tyrosine kinase enzymes. On the x axis is the micromoles of Gleevec on a log scale from 0.001 to 100. On the y axis is the percent inhibition of kinase activity. The lines all follow different trajectories, often rising and falling multiple times. Dashed lines indicate that c A b l reaches 50 percent inhibition at a concentration of 0.2 micromolar Gleevec. Other dashed lines indicate that c F m s reaches 50 percent inhibition at a concentration of approximately 6 micromolar Gleevec. All other kinases reach 50 percent inhibition at greater than 10 micromolar Gleevec.

Figure 17.18 Dose response curves of Gleevec The ability to inhibit a targeted protein without affecting other, related cellular proteins is critical to the success of therapy, making possible therapeutic responses without undesired side-effect toxicities. Here we see the responses of a group of six tyrosine kinase (TK) enzymes to the drug Gleevec (see Figure 17.13). In all cases, the kinase activity of the purified enzymes in solution was measured. Note that the graph was

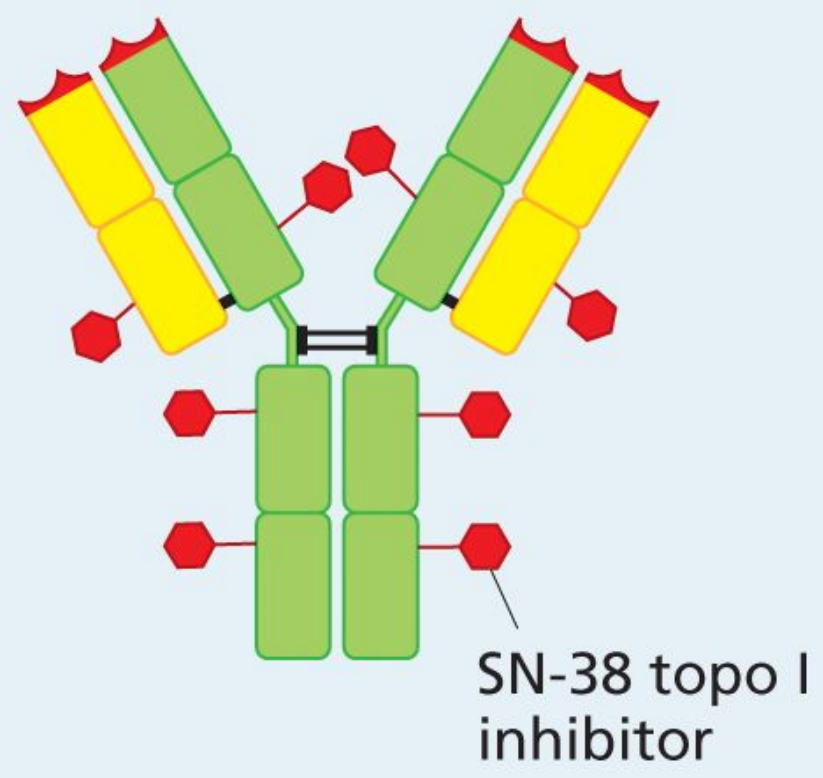
constructed using the log of Gleevec concentration on the abscissa; the percent of inhibition of catalytic activity is plotted linearly on the ordinate. A level of 50% inhibition is indicated by the *green dashed horizontal line*. At a concentration of approximately 0.2 μM (*blue dashed vertical line*), 50% of c-Abl enzyme activity was inhibited, whereas comparable inhibition of the c-Fms TK occurred only at a concentration of ~6 μM (*brown dashed vertical line*). Under these conditions, the c-Src TK was hardly inhibited at all. (Courtesy of Novartis Pharmaceuticals.)

In the case of tyrosine kinase inhibitors, which are the focus of much current anti-cancer drug development, new experimental strategies are being developed to enable the screening of a large portion of the kinases that might possibly be affected by a candidate drug inhibitor. Technologies like the one described in **Supplementary Sidebar 17.8** greatly accelerate the rate at which large numbers of candidate drugs can be tested against a wide spectrum of these enzymes. As we will see later, discovering off-target activities of a drug, which is enabled by screens such as this one, is actually useful in two ways: (1) It may explain toxicities of a drug—undesired side effects in tissues other than the targeted tumor; and (2) it may reveal new clinical applications for the drug, because the drug may be found to inhibit an enzyme, such as a kinase, that is active in a type of tumor that was not targeted during the initial drug development (**Sidebar 17.8**).

Sidebar 17.8 Linking cancer drugs together

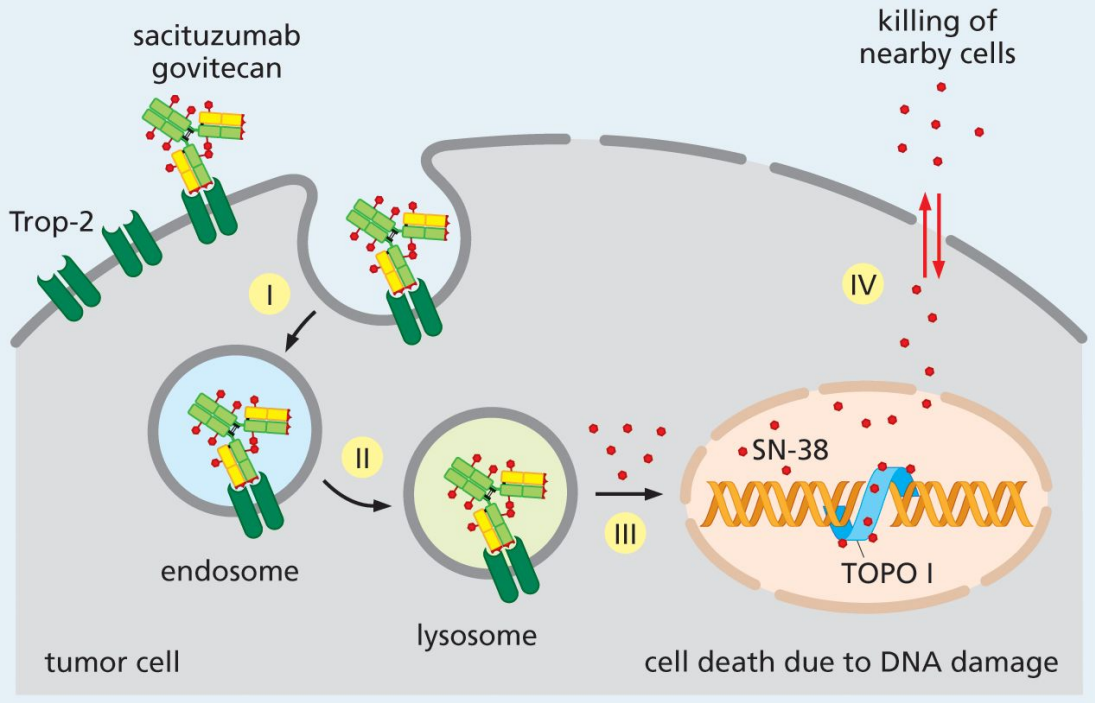
In addition to drug derivatization, another type of drug engineering involves the physical linking, usually via covalent bonds of multiple agents to produce combinatorial effects. The potential benefit of such an approach is twofold. First, it can ensure that both constituent agents are present in a target tumor cell at a desired stoichiometric ratio. Second, if one component of the conjugate can provide tumor targeting, a second, more toxic, drug can be delivered specifically to tumor cells (while sparing normal cells). An example of this approach, discussed in Chapter 16, is the development of antibody–drug conjugates targeting the transmembrane glycoprotein Trop-2—a protein found on the surface of many epithelial tumors. As discussed previously in this text (see Figure 4.3), monoclonal antibodies (most notably those targeting Her2/neu) are a central component of combination drug regimens used for the treatment of breast cancers, that is, breast tumors that overexpress this protein. However, these regimens are generally unsuccessful in the treatment of metastatic breast cancer, and resistance to antibody therapy can arise in primary tumors through multiple alternative mechanisms. Similar to trastuzumab (anti-Her2/neu)-chemotherapy conjugates described in Chapter 16, the antibody–drug conjugate sacituzumab govitecan (or Trodelvy), an antibody–drug conjugate that links hRS7 (a Trop-2 antibody) to SN-38, a topoisomerase I poison has been approved for the

treatment of metastatic breast cancer. In this case, hRS7 binding to Trop-2 promotes receptor-mediated internalization of the conjugate, followed by release of the SN-38 “payload” (**Figure 17.19**). Thus, high doses of a chemotherapy that would typically elicit toxic effects in nonmalignant cells can be more specifically delivered to tumor cells. This agent has extended survival in disseminated, treatment-refractory breast cancer and represents one of a large number of antibody-targeted therapies that are currently in clinical development. These therapies provide some hope for alternatives to the standard systemic treatment of cytotoxic chemotherapy and its accompanying side effects.



A diagram of a Y shaped antibody with S N 38 topo 1 inhibitors bound to it.

(A)



A diagram shows the process of an antibody drug conjugate killing a tumor cell. The antibody drug conjugate labeled sacituzumab govitecan binds to a Trop 2 receptor on the tumor cell membrane. The antibody drug conjugate is brought into the cell in an endosome. The endosome becomes a lysosome. This releases S N 38 molecules which enter the nucleus and inhibit TOPO 1. This causes cell death due to D N A damage. S N 38 molecules are released and go on to kill nearby cells.

(B)

Figure 17.19 Targeting chemotherapy to cancer cells (A) Multiple copies of the topoisomerase I poison SN-38 (*pink dots*), are bound to an antibody molecule targeting Trop-2, a surface protein displayed on the surface of many epithelial tumor cells. This antibody–drug conjugate, termed sacituzumab govitecan (Trodelvy), has been approved for clinical treatment of patients suffering from metastatic triple-negative breast cancer. SN-38 molecules are tethered to the Trop-2 antibody with a stoichiometric ratio of 7.6 to 1, allowing elevated levels of the cytotoxic chemotherapy compound to be delivered, as a payload, to individual cancer cells. (B) I. Upon engaging the Trop-2 cell-surface protein, the antibody–drug conjugate is internalized into the tumor cell via endosomal trafficking. II. The linker joining SN-38 to the antibody is hydrolyzed in the lumen of an endosome. III. SN-38 molecules are released, enter the nucleus, and inhibit topoisomerase I (TOPO I), yielding cell killing. IV. SN-38 molecules are released from the dying cell to enter and kill nearby cancer cells via “bystander effect

killing." (Adapted from https://www.futuremedicine.com/doi/10.2217/fon-2020-0163. H.S. Rugo et al., *Future Oncol*. 16, 2020. With permission from Hope S. Rugo.)

Glossary

stereochemistry
: Description of the three-dimensional structure of a molecule (such as a protein or drug) and the influence that this structure exerts on the chemical behavior or biochemical function of the molecule.

derivatization
: The alteration via synthetic organic chemistry of the molecular structure of an existing drug molecule, usually through the covalent linkage of side groups, and undertaken with the intention of improving its pharmacological properties.

17.7 Drug candidates and their targets must be examined in cell models as an initial measurement of their utility in whole organisms

The early development of cytotoxic chemotherapy occurred with little understanding of the mechanisms of action of these agents. Instead, the ability of these agents to preferentially kill cancer as opposed to normal cells was sufficient on its own to warrant exploration of their clinical potential as cancer therapeutics. In contrast, the generation of rationally targeted therapies involves two independent but converging lines of experimentation that are used to support continued pre-clinical development.

The first and more recent of these involves the use of genetic tools to explore the potential effects of targeting a particular protein in distinct cellular contexts, that is, inactivating this protein through directed alteration of its encoding gene. This process has been significantly enabled by the development of gene suppression tools, such as RNA interference and, more significantly, gene editing using CRISPR/Cas9 systems adapted from prokaryotes. The ability to genetically inactivate or entirely eliminate the expression of any gene of interest enables one to identify cell vulnerabilities in diverse cellular contexts. Thus, the knockout of a gene of interest creates a model of what would likely happen in a cell or tissue if a drug completely inactivated the functions of its encoded protein product. Moreover, this approach can determine whether cells from various tumor types or bearing particular genetic alterations are more or less sensitized to the loss of a particular gene function (**Sidebar 17.9**).

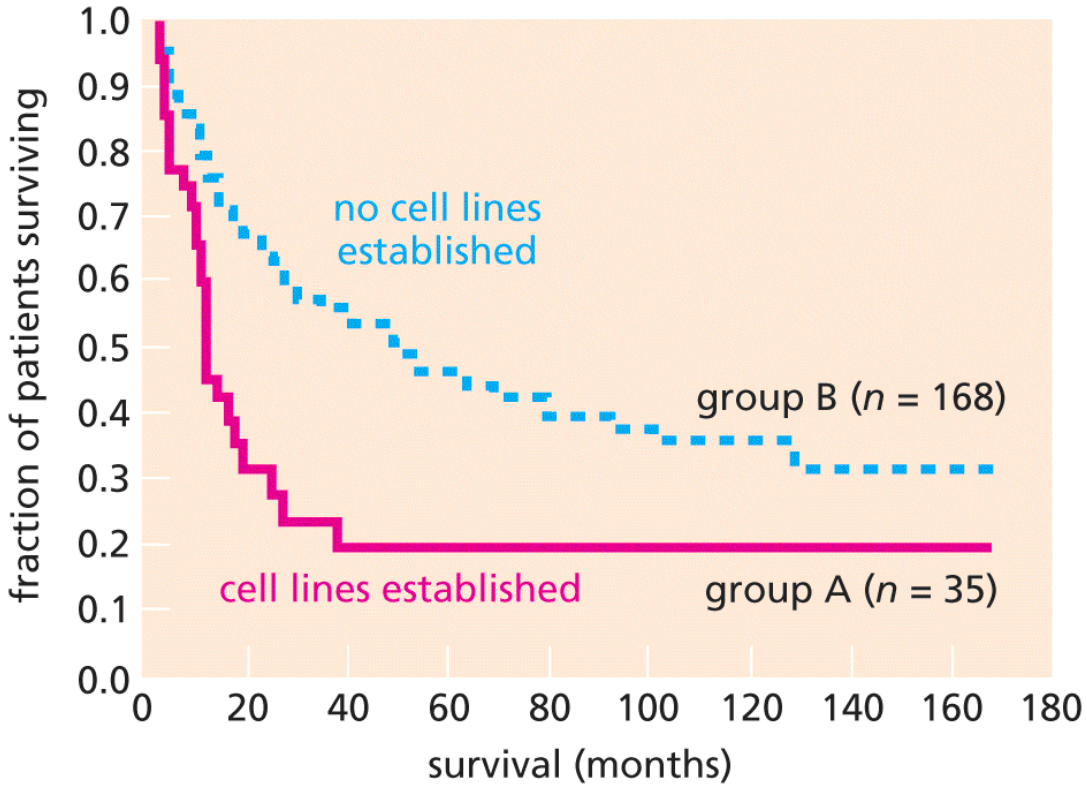
Sidebar 17.9 Systematic screening and the Cancer Dependency Map

In a more ambitious effort applying gene-editing tools to survey cancer-related genes, large-scale projects like the DepMap (or Cancer Dependency Map) have used CRISPR/Cas9 to systematically disrupt all genes in the human genome in each of a large collection of human tumor cell lines, doing so in order to identify specific genes whose continued function is critical to the proliferation or viability of the cells forming each of these cell lines. This expansive database now includes information examining over 27,000 genes in 1811 cell lines derived from 35 distinct primary diseases. Data from these efforts can not only validate the choice of a particular protein as a target for

future development but can also identify specific contexts, such as classes of cancers, in which the drug may be most effective.

The powers of the DepMap, as described above, can help address major questions of pre-clinical cancer research, notably whether targeting a particular protein would have an effect in treating a particular cancer, and which particular tumor types and patients would benefit from treatment with one or another drug. Still, this approach does have some notable limitations. For example, the cellular consequences of eliminating a protein from cells, as revealed by CRISPR/Cas9-mediated gene editing, may be dramatically different from those incurred by small molecule drug inhibition of the same protein from such cells. In addition, this approach only models cancer cell-intrinsic effects of a particular therapeutic drug, while failing to register drug effects on tumor-associated stromal cells, whose functions may also contribute in critical ways to the responses of the tumor as a whole. Finally, the DepMap, at least in its initial incarnation, focuses on cancer cell lines propagated *ex vivo*, some of which deviate significantly from corresponding cancer cells prepared directly from tumors, raising the question of the possibly limited utility in predicting drug sensitivities of various types of cancer cells.

The second major line of pre-clinical experimentation and certainly the more time-honored and established strategy—involves determination of the effects of drugs on cancer cells propagated in tissue culture. Here, the choice of cultured cells represents a major challenge (see also Sidebar 13.2). Many cell lines have been propagated in culture as pure populations for many years, often decades. As a prominent example, many small molecules were initially evaluated in a set of 60 human cancer cell lines established by the National Cancer Institute as standard reagents to be used for gauging the efficacy of candidate anti-cancer agents. Many of the cell lines from this "NCI-60 cell lines" panel are not representative of neoplasms encountered routinely in the cancer clinic because they derive from particularly aggressive human tumors that yielded cells that were especially adaptable to extended propagation in tissue culture (as shown in **Figure 17.20**). Other cancer cell lines have, almost inevitably, evolved in culture far beyond the ancestral cells that were originally removed from actual human tumors; consider that the cells in such lines have been selected for optimal proliferation under *in vitro* conditions that differ profoundly from those in living tissues.



A graph of the survival of cancer patients from which cells were extracted. Survival in months is on the x axis and the fraction of patients surviving is on the y axis. For the 35 patients where cell lines were established, the fraction of patients surviving drops quickly to 0.2 by 20 months, and from there it stays constant. For the 168 patients where no cell lines were established, the fraction of patients surviving drops more slowly to 0.3 by 130 months, and from there it stays constant.

Figure 17.20 Cancer cell lines as representatives of human tumors Many researchers have attempted to create cancer cell lines by extracting cells from human tumors and adapting them to culture. Their experience, largely anecdotal, is that only the most malignant cancer cells can be propagated *in vitro*, yielding cancer cell lines. This notion has finally been tested systematically in a 12-year-long study in which the esophageal carcinoma cells of 203 patients were introduced into culture. Of these, only 35 cell lines (derived from about 17% of the tumors) became established in culture. The patients whose tumors were in this group (group A) experienced a far worse clinical progression (*red line*) than did those whose cells failed to adapt to culture (group B; *blue line*). This study illustrates graphically why tumor xenografts produced from established cancer cell lines usually fail to recapitulate the properties of the tumors typically encountered in a cancer clinic (because the cancer cell lines usually derive from tumors at the far end of the clinical spectrum—the most aggressive subset). (From Y. Shimada

et al., *Clin. Cancer Res*. 9:243–249, 2003. With permission from American Association for Cancer Research.)

This situation has now changed. The ability to culture diverse sets of tumor-derived cells has evolved rapidly over the past two decades. In particular, the use of specialized media and co-cultured stromal support cells has made it possible to propagate *in vitro* a diverse set of tumor cell types that previously resisted propagation in culture. These advances have enabled systematic efforts to catalog the effects of large sets of cancer drugs on an increasing number of cancer cells. These efforts, which include the Cancer Cell Line Encyclopedia (CCLE) and the Genomics of Drug Sensitivity in Cancer (GDSC), now serve as general resources for evaluating the efficacy and specificity of cancer drugs in an extended array of cancer cells with defined genetic alterations.

Additionally, the ability to grow tumor cells in three-dimensional clusters, termed organoids (see **Supplementary Sidebar 11.9**), has made it possible to replicate more closely the treatment conditions experienced by neoplastic cells growing in tumors *in vivo*. In certain cases, the cancer cells growing in organoids exhibit dramatic differences in drug response relative to their behavior when grown in two-dimensional culture. These advances in cell propagation technology now allow a greater diversity of tumor types bearing a broad set of underlying mutations to be examined in the context of new therapies. However, the adaptation of cells to growth in culture, even when performed rapidly and in carefully orchestrated contexts, is likely to be accompanied by significant changes in the cultured cells that are likely to affect drug responses (**Sidebar 17.10**).

Sidebar 17.10 Pitfalls in identifying proteins and signaling pathways for pharmacological targeting

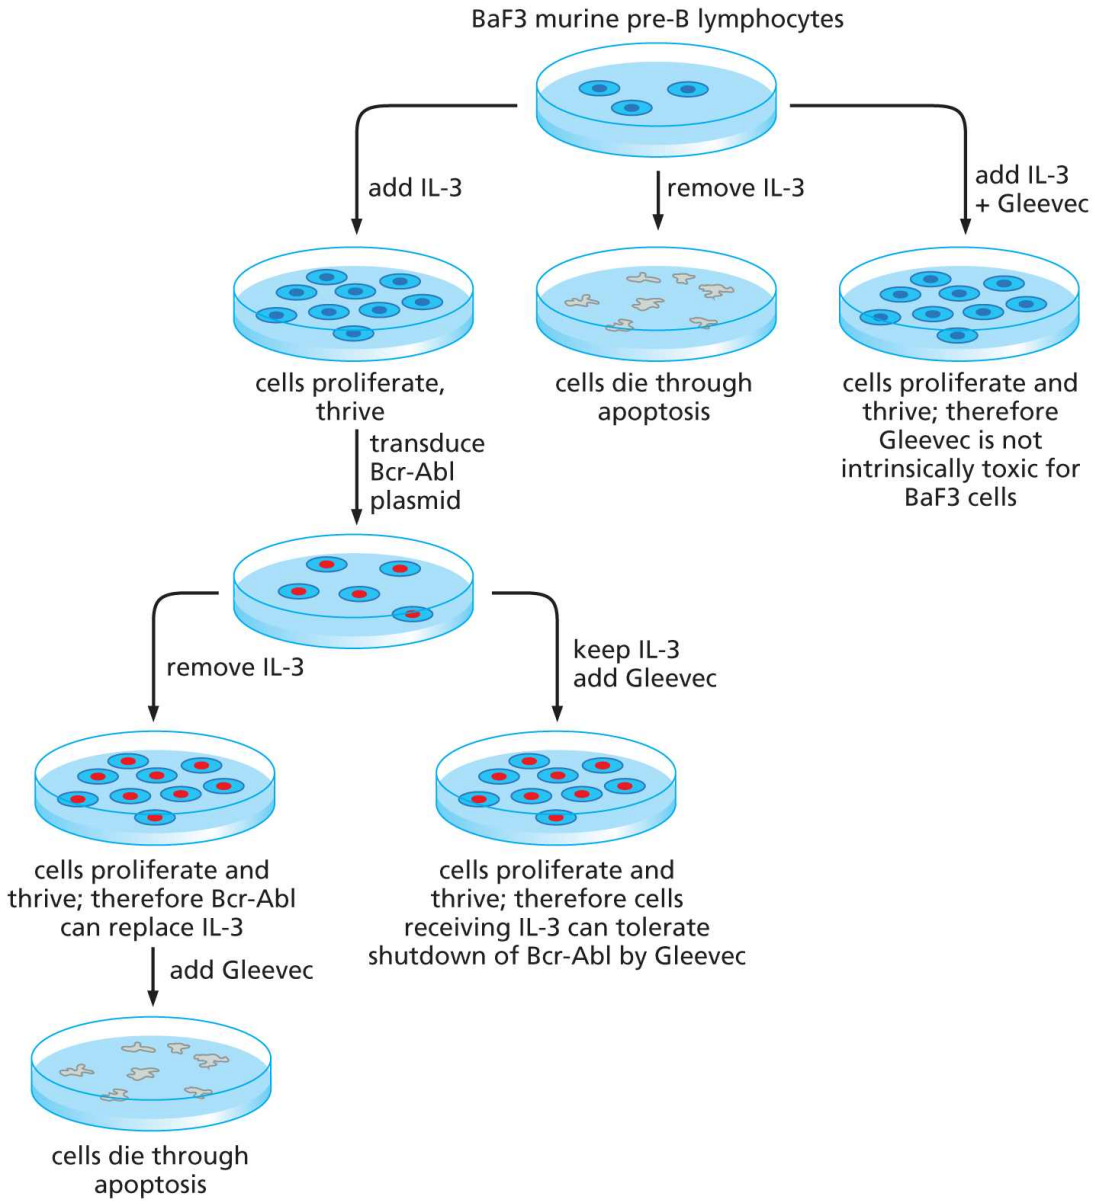
Identifying a protein or pathway as a good cancer target for anti-cancer drug development is a challenging, but critically important, task. Thus, the landscape of anti-cancer drug development projects is strewn with many that ultimately failed. How can one avoid the pitfalls that have determined the fate of these projects? Here, lessons can be learned from the development of the failed projects. Especially instructive is the history of developing inhibitors of the hedgehog (Hh) signaling pathway (see Figures 5.17 and 6.22C). Hedgehog signaling plays a key role in organismal development and cell differentiation, and defects in this pathway lead to aberrant development of a diverse set of organisms. Analysis of Hedgehog signaling in various types of tumors suggested a role for this pathway in the growth, proliferation, and invasion of individual tumor cells. Indeed, it was postulated that Hh inhibitors might have efficacy in more than 25% of all human cancers. As a result, at least 10 different Hh pathway-

inhibiting small molecules (that is, drug molecules of specific structure) were generated by drug companies using organic chemistry synthesis. Based on extensive pre-clinical testing in cancer cell lines and animal models, 86 human clinical trials were ultimately launched. However, except for a small subset of basal cell carcinomas of the skin and medulloblastomas (many adult-onset versions bear activating mutations in the Hh pathway), Hh inhibitors failed to yield any clinical benefit.

So where precisely did the pre-clinical studies go wrong? Although many issues have played a role in the lack of success of these agents, one clear and major contributor was the data generated from studies examining the effects of candidate drugs on tumor cells lines propagated in culture. Tumor cell lines were generally treated with very high doses of Hh pathway inhibitors, significantly higher than those necessary to inhibit signaling through the Hh pathway. As a direct consequence, many of the observed effects of these agents were related to nonspecific or Hh-independent effects, and comparable doses (as gauged by drug concentrations delivered *in vivo*) could not be physiologically achieved in patients. Here, one wonders whether genetic studies validating the dependency of specific tumor cell lines on this pathway using gene editing technology that is currently feasible may have halted the drug development process at an earlier juncture, long before costly clinical studies were considered and implemented.

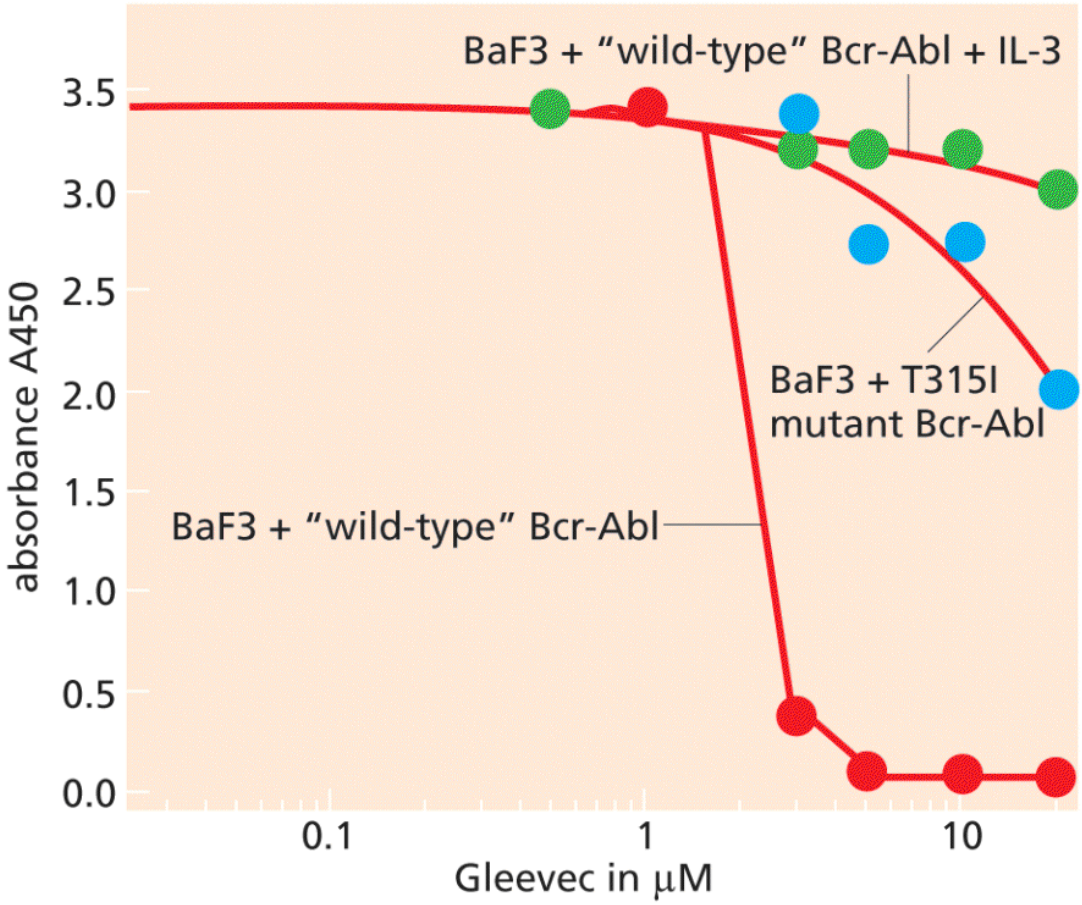
Cell culture studies are generally undertaken after biochemical studies have validated drug–target interactions, that is, the engagement of a candidate drug molecule by an identified protein target. Here we can learn much from the case of Gleevec, the compound (see Figure 17.13A) found initially to inhibit the tyrosine kinase activity of the isolated Bcr-Abl fusion protein; this protein was known to be responsible for driving the proliferation and survival of the cancer cells of chronic myelogenous leukemia (CML; see Figure 4.11). Having established its effects on the isolated Bcr-Abl protein (see Figure 17.14), drug developers could then proceed to the next step, which involved the use of cultured cells whose proliferation or survival *in vitro* depended on the continued actions of this fusion protein.

Figure 17.21A shows an example of such a cell-based test, which happens to have been conducted long after Gleevec was developed. This test used the cells of a murine pre-B-lymphocyte line that normally depend for their survival and proliferation *in vitro* on the presence of interleukin-3 (IL-3) in their culture medium. These cells could be rendered independent of IL-3 if a functional Bcr-Abl oncoprotein was ectopically expressed in them. The modified cells were then cultured in the absence of IL-3 (making them totally dependent on continued Bcr-Abl firing) and exposed to various drugs that were candidate antagonists of the Bcr-Abl oncoprotein. The proliferation and survival of these cells was then gauged (Figure 17.21B).



A flow chart shows the process of testing B a F 3 murine pre-B lymphocytes grown in a petri dish. If I L 3 and Gleevec are added, cells proliferate and thrive. Therefore, Gleevec is not intrinsically toxic for B a F 3 cells. If I L 3 is removed, the cells die through apoptosis. If I L 3 is added, the cells proliferate and thrive. If those cells are then transduced with the B c r A b l plasmid, a new strain of cells is created. If Gleevec is added in the presence of I L 3, these new cells proliferate and thrive. Therefore cells receiving I L 3 can tolerate shutdown of B c r A b l by Gleevec. Additionally, if I L 3 is removed, the cells proliferate and thrive. Therefore B c r A b l can replace I L 3. However, if Gleevec is added after I L 3 is removed, the cells die through apoptosis.

(A)



A scatterplot shows the survival of cells in different conditions when treated with increasing Gleevec concentrations. On the x axis is the Gleevec concentration in micromoles from 0 to 10 on the log scale. On the y axis is absorbance A 450 from 0 to 3.5. All three conditions start with a high absorbance. Around a concentration of 2 micromolar, the absorbance of the B a F 3 plus wild type B c r A b l cells drops quickly, and by a concentration of 8 micromolar, the absorbance is 0. The other 2 cell lines decrease as well but more gradually. The B a F 3 plus T 315 I mutant B c r A b l cells decreases to an absorbance of 2 at greater than 10 micromolar. The B a F 3 plus wild type B c r A b l plus I L 3 cells decreases to an absorbance of 3 at greater than 10 micromolar.

(B)

Figure 17.21 Testing of Gleevec in cell culture (A) BaF3 cells, a line of murine pre-B lymphocytes, normally depend on the addition of interleukin-3 (IL-3) for their proliferation and survival (*top left*). When Gleevec is added together with IL-

3, these cells continue to thrive (*top right*), indicating that the IL-3–based survival mechanism is not sensitive to Gleevec inhibition. When an expression plasmid specifying the Bcr-Abl oncoprotein is also introduced into these cells, the BaF3 cells continue to proliferate, even after IL-3 is withdrawn (*left middle*), indicating that Bcr-Abl can replace IL-3 and sustain these cells on its own. However, the addition of Gleevec at doses that inhibit the Abl kinase will cause the cells to die (*lower left*), whereas addition of Gleevec to Bcr-Abl–expressing cells that continue to receive IL-3 does not affect their survival. Therefore, in the absence of IL-3, the Bcr-Abl–expressing BaF3 cells can serve as highly sensitive and specific indicators of the actions of Gleevec and similarly acting drugs on the Bcr-Abl oncoprotein. (B) The information in panel A can be used to develop an assay system, in which the number of BaF3 cells surviving after certain treatments is indicated by the optical density (absorbance at 450 nm wavelength) of BaF3 cell suspensions (*ordinate*). In the presence of IL-3, Gleevec has almost no effect on BaF3 cell survival, whether or not the Bcr-Abl oncoprotein is being expressed in BaF3 cells (*green dots*). In the absence of IL-3, however, survival of Bcr-Abl–expressing cells is strongly suppressed above about 2 μM Gleevec concentration (*red dots*). If instead of the "wild-type" Bcr-Abl protein, cloned from a patient's CML cells at the beginning of Gleevec treatment, a highly drug-resistant mutant version of Bcr-Abl (termed T315I) that arose in a CML patient during the course of Gleevec treatment is expressed in the BaF3 cells growing in medium lacking IL-3, far higher drug concentrations are required to kill these cells (*blue dots*). (Courtesy of M. Azam and G.Q. Daley.)

Cell-based tests like these are designed to determine whether the drug being examined induces apoptosis in treated cells, or cytostasis (that is, a halt in cell proliferation), or has no effect whatsoever. And if the drug does evoke a desired response, does it do so at a reasonably low concentration?

The outcomes of such cell-based tests are rarely obvious beforehand. Many compounds that are highly hydrophobic may be excluded from these tests from the outset because they are poorly soluble and therefore cannot be placed on cultured cells in significant concentrations. Their more hydrophilic chemical relatives may be highly soluble and may work well on a purified targeted protein, such as Bcr-Abl, but may not be readily transported through the plasma membranes of cells; these chemical species are likely to prove useless, simply because they cannot accumulate within cells at concentrations that would allow them to be effective (see **Supplementary Sidebar 17.6**).

Imagine that these hurdles have been successfully surmounted and that the proliferation of Bcr-Abl–dependent cells is indeed inhibited at nanomolar concentrations of a candidate therapeutic agent. Although the candidate drug acts on

these cells, it does not exclude the possibility that the drug also affects dozens of other kinases in these and other cells, some of which may be essential for normal cell metabolism—the property of biological selectivity or lack thereof. (Its *biochemical* selectivity is likely to have been determined previously by tests such as those described in **Supplementary Sidebar 17.8**).

Given the initial lack of certainty about the selectivity of a candidate Bcr-Abl drug, it became necessary to determine whether cancer cells whose growth is driven by other tyrosine kinases were equally sensitive to the actions of an identified anti-Bcr-Abl agent like Gleevec and whether fully normal cultured cells were affected by a candidate drug like Gleevec. With luck, one might begin to see a high therapeutic index emerge; for example, in the context of the assay described in Figure 17.21, Bcr-Abl–dependent cells might have been killed by drug concentrations that had little discernible effect on comparable cells grown in the presence of IL-3 or on a variety of other cancer cells whose growth is driven by other tyrosine kinase oncoproteins. Such observations would provide hope, as they did in the case of Gleevec development, and would encourage the drug developers to proceed to the next steps, in which the biological effects of drugs at the cellular and tissue level are evaluated *in vivo*, as we learn below.

OceanofPDF.com

Glossary

Cancer Dependency Map
: The product of an effort focused on systematically cataloging the key roles of genes throughout the entire human genome whose inactivation by CRISPR/Cas9 leads to the death of cells belonging to specific cancer cell lines.

NCI-60 cell lines
: (often **NCI-60**) The collection of 60 human cancer cell lines prepared from nine commonly occurring tumor types and provided by the U.S. National Cancer Institute that is often used to gauge the responsiveness of different types of cancer cells to therapeutic agents under development.

organoid
: An experimentally created model of a normal adult tissue, usually generated through incubation of organ-specific stemlike cells suspended in a three-dimensional gelatinous matrix containing a cocktail of factors designed to induce a tissue-specific differentiation program in the organoid.

17.8 Studies of a drug's action in laboratory animals are an essential part of pre-clinical testing

Once a candidate anti-tumor agent has been found to have potent killing effects on cultured cancer cells *in vitro*, drug development inevitably moves to the next step—testing whether it will kill cancer cells proliferating within tumor masses *in vivo*. Ideally, the *in vitro* behavior of a drug should predict its actions *in vivo*.

In fact, the *in vivo* treatment environment introduces additional complexities governing therapeutic response that are not present in the cell culture setting. One is suggested by experimental results that we encountered in Section 13.9. There we read that the sensitivity of tumors to radiation may be determined by the radiosensitivity of the endothelial cells in their vasculature, rather than by the responses of the neoplastic cells in these masses; some drugs may act similarly, by affecting the supporting stromal cells of a tumor (which are rarely studied *in vitro*) rather than the cancer cells themselves. For example, endothelial cells exposed to the DNA-damaging effects of certain cytotoxic drugs respond by releasing interleukin-6 (IL-6), which confers on nearby lymphoma cells an elevated resistance to killing by these drugs. (This finding may explain why lymphoma cells in a mouse model of Burkitt's lymphoma can survive chemotherapy by finding refuge in the thymus, where this pro-survival signal is produced in abundance by the resident endothelial cells.)

Independent of such therapy-induced responses, stromal cells may continuously provide certain types of anti-apoptotic survival signals, such as IGF-1, that are not available in comparable amounts to cancer cells in culture (see Figure 9.32). In a more general sense, the complexities of tumor biology created by heterotypic interactions of neoplastic cells with the tumor-associated stroma often dictate that the drug responses of pure populations of cancer cells proliferating *in vitro* fail to predict their responses within growing tumors *in vivo*.

Because rodent and human cells can differ so substantially in their biology (see Section 11.9), the *in vivo* testing of candidate anti-cancer drugs involves, almost

always, human (rather than murine) cancer cells grown in mouse hosts. The presumption is that the human tumor xenografts formed in immunocompromised mice will behave much like the tumors encountered by oncologists in human patients. However, almost always these tumors are derived from cells that have previously adapted to growth in culture (as discussed above), are frequently implanted in anatomical sites in mouse hosts that are distinct from their tissue of origin, exhibit species-specific differences in the types of recruited stromal support cells, and grow well only in the absence of a functional immune system.

These facts help to explain why human tumor xenograft models (that is, human tumor cells growing in foreign hosts, usually mice) are relatively unpredictive of the responses of the actual tumors borne by patients in the cancer clinic. Indeed, in some cases, it is questionable whether cancer cells that are purportedly from, for example, a pancreatic carcinoma continue to reflect pancreatic behavior, or whether they have been inadvertently contaminated by colon or breast carcinoma cells at some point over the previous several decades of *in vitro* passage in one or another laboratory. In addition, there are clear indications that human tumors growing as xenografts in mice interact with the host tissue microenvironment in a fashion that differs from mouse tumor xenografts interacting with syngeneic host tissues (**Sidebar 17.11**).

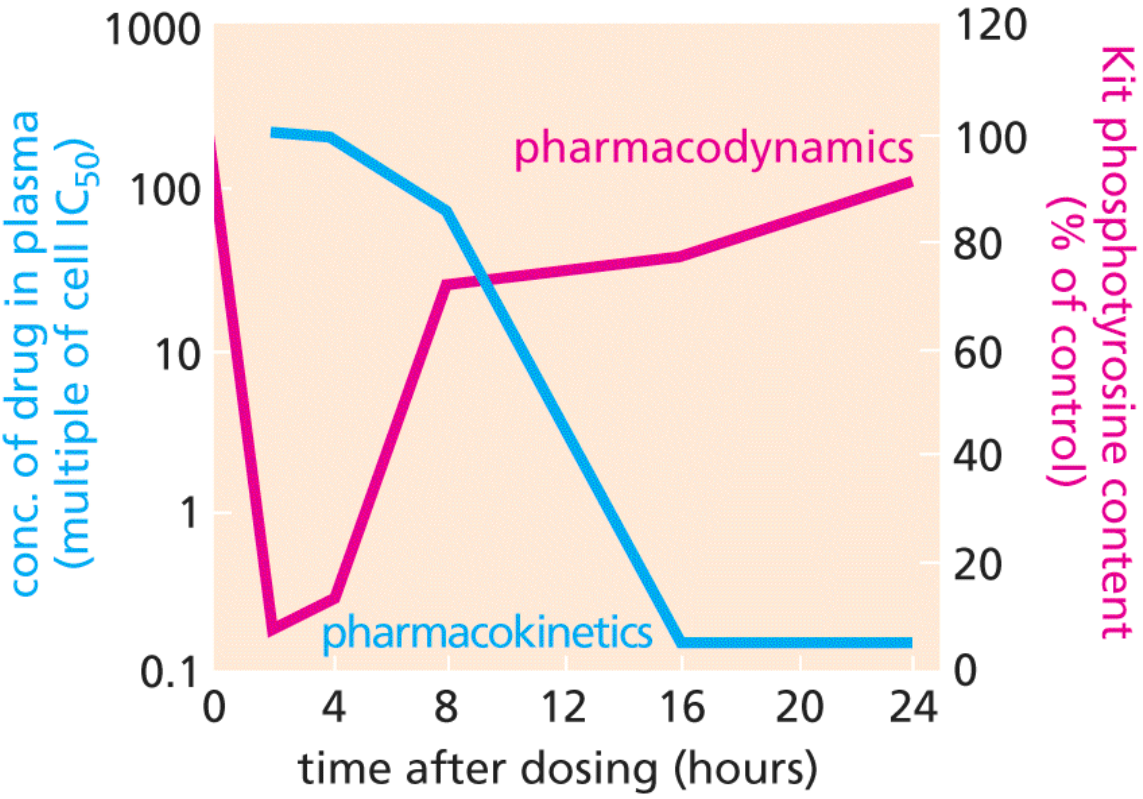
Sidebar 17.11 The elusive, ideal, pre-clinical model of drug responses

There is yet another problem that, until recently, has not attracted attention. In 2009 experiments were reported on a genetically engineered mouse model (GEMM) of pancreatic adenocarcinoma development; this research analyzed the responses to therapy of such tumors arising within mice through the actions of oncogenic alleles introduced into their *K-ras* and *p53* germ-line genes. The resulting autochthonous tumors (that is, those arising within a host rather than being implanted in such host) that formed in these mice responded to therapy very differently from tumors that arose when the cells from these autochthonous tumors were extracted, propagated briefly in culture, and then implanted subcutaneously in other syngeneic host mice, now forming pancreatic tumor grafts. This finding pointed to another long-neglected problem—namely, that experimentally implanted tumor grafts may behave very differently from autochthonously arising tumors, even when the two tumor cell populations are genetically indistinguishable from one another. [In this case, the implanted tumors were responsive to gemcitabine therapy (see Figure 17.7), whereas the autochthonous tumors were resistant.] If this observation were generalized to

other tumor models and cancer types, it would greatly complicate pre-clinical drug testing because implantation of tumor cell lines is far simpler logistically and less expensive than GEMM models of disease.

Indeed, the challenge of finding the ideal pre-clinical mouse model may not have a single solution. There is now an abundance of readily available mouse models to test therapeutics. These models include the use of orthotopic injections of syngeneic tumor cells, the injection of human tumor organoid cell cultures, the use of "humanized" mouse models in which tumors arise in the context of a human organ system reconstituted in a mouse, and the use of mice bearing humanized immune systems. All these systems have potential advantages, but none truly recapitulate the clinical setting in human cancers.

As discussed earlier, the pharmacokinetics (PK) of a drug represent a key determinant of its efficacy *in vivo*: Does it accumulate to significant levels in the plasma or tissues for an extended period? Or is it present in the body only transiently, being excreted by the kidneys within minutes of entering into the circulation? Is it resistant to rapid degradation, or do certain drug-metabolizing systems, such as the cytochrome P450s (see Section 12.5), rapidly convert it into an innocuous, chemically unreactive molecular species (**Figure 17.22**)? (A key pharmacokinetic parameter that is often measured is the "area under the curve," or AUC, which is calculated by integrating the concentration of a drug in the plasma as a function of time; the AUC is thought to reflect the cumulative drug dose experienced by cells in a tumor.) And can it be administered orally rather than requiring injection?

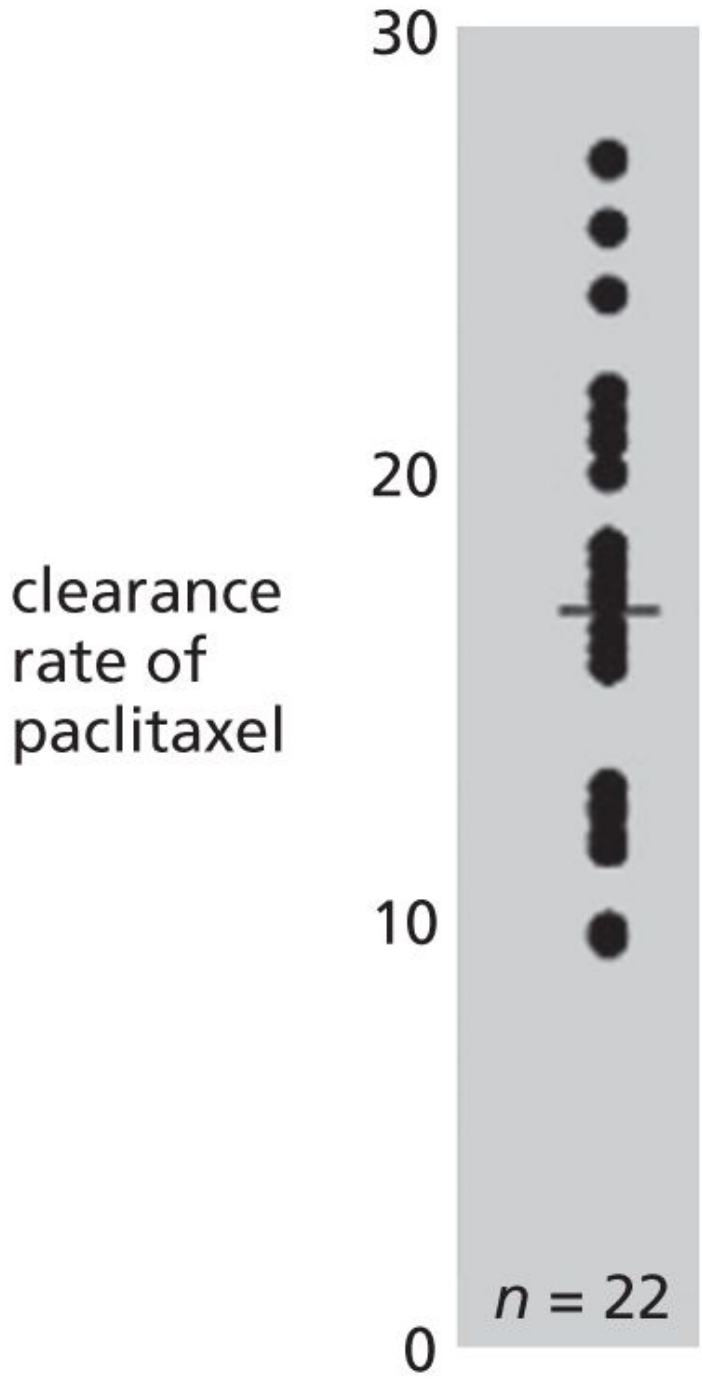


A line graph shows the change in concentration of Gleevec in plasma and the Kit phosphotyrosine content over time. The x axis has time after dosing from 0 to 24 hours. The concentration of Gleevec starts above 100 and decreases to 0.1 by hour 16. The Kit phosphotyrosine content, as a percent of control, starts near 100, decreases to around 0 by hour 2, increases to 80 by hour 8, and increases more slowly to 95 by hour 24.

Figure 17.22 Pharmacokinetics and pharmacodynamics of Gleevec The pharmacokinetics of a drug represent the kinetics of its accumulation in and disappearance from the plasma, which in turn are presumed to provide a good indication of the drug concentrations that tumor cells experience in a laboratory animal or a patient undergoing therapy. The plasma level of the drug Gleevec, plotted on a logarithmic scale (*left ordinate*), fluctuates dramatically following injection of the drug into a mouse (*blue curve*). Its concentration is indicated here as a multiple of the drug concentration known to inhibit the firing of the tyrosine kinase of the Kit receptor by 50% (i.e., the IC_{50} of this agent). (The tyrosine kinase domain of the Kit growth factor receptor is also a target of inhibition by Gleevec.) In order to gauge the pharmacodynamics, the amount of phosphotyrosine associated with the Kit receptor (a reflection of Kit tyrosine kinase activity) was measured, in this

case the Kit expressed by engrafted human mast cell leukemia cells (*red curve*), which was initially set as 100%. It decreases to <<1% of pre-existing levels within an hour after drug injection but rebounds within 8 hours as the concentration of the drug declines in the plasma. (Courtesy of D.L. Emerson.)

Laboratory animals give some rough indication of a drug's pharmacokinetics, but they are by no means accurate predictors of how humans metabolize and excrete various agents. Moreover, as we read earlier (see Sidebar 12.4), the rates at which various compounds are metabolized or excreted can even vary dramatically from one person to another (**Figure 17.23**). (In some pharmaceutical companies, the pharmacokinetics of candidate compounds may be measured even *before* their therapeutic efficacy against xenografted tumors is assessed; those showing poor pharmacokinetics in laboratory animals are often eliminated from further testing. Discarding such drugs may occasionally be premature, given the dramatically differing rates of drug metabolism and excretion between rodents and humans.)



A figure shows the clearance rate of paclitaxel in 22 patients. The clearance rates range from 9 to 28.

Figure 17.23 Inter-individual variability in drug clearance Paclitaxel is a chemotherapeutic drug used to treat a number of malignancies; it works by stabilizing microtubules, thereby interfering with the progression of cells

through M phase (see Figure 17.7). As seen here, in this study of 22 ovarian cancer patients, the relative rates of clearance of this drug from the plasma after initial injection varied over a factor of 3. These rates may be influenced by changes in the rate of metabolism by enzymes such as cytochrome *c* (see Figure 12.13) and by excretion in the kidneys. (From M. Nakajima et al., *J. Clin. Pharmacol*. 45:674–682, 2005. With permission from John Wiley & Sons.)

Figure 17.22 illustrates the other key kinetic process that was introduced earlier—a drug's pharmacodynamics (PD), in this case those of Gleevec. Recall that pharmacodynamics measure the ability of a drug to affect a targeted biochemical or cell-biological function in a tumor under treatment. In the PD presented in this figure, as is often the practice, a surrogate marker of the targeted Bcr-Abl function was measured—the behavior of the Kit receptor. Kit is one of several tyrosine kinases affected by Gleevec, and its responses to the drug presumably parallel those of Bcr-Abl. Figure 17.22 reveals that Kit activity in this experiment was inhibited only briefly at the time when the highest concentration of drug was present in the circulation. Such a transient inhibition—only a fraction of a cell cycle—is generally insufficient to elicit a substantial biological response, such as tumor cell killing.

During the course of animal testing, information may surface about the toxic side effects that the drug elicits in whole organisms. These side effects represent the bane of almost all existing cancer treatments. Quite frequently, various normal organ systems, including the liver, kidneys, gastrointestinal tract, and the hematopoietic system, show toxic effects of a drug when it is used at the concentrations required to kill tumor cells. These toxicities are rarely predicted by *in vitro* tissue culture tests, and toxicities detected in laboratory animals, including dogs, monkeys, mice, and rats, may or may not be predictive of human responses. For example, when used together with a cytotoxic drug to treat subtypes of breast and gastric carcinomas, Herceptin (also known as trastuzumab), a monoclonal antibody that is reactive with the HER2/neu receptor, has an effect on cardiac function that could not have been predicted from the known expression of the HER2/neu receptor in various epithelial cell types; this effect can lead to (usually reversible) heart failure in a significant fraction of patients under treatment.

Such observations direct our attention once again to the therapeutic index of an agent—the efficiency with which it affects cancerous tissues compared with its

toxic effects in normal tissues. Clearly, ideal cancer treatments should have high therapeutic indices, wreaking havoc on cancer cells while leaving normal tissues relatively untouched. The fundamental obstacle to achieving such selectivity is that most of the 11,000 or so genes expressed in the average cancer cell are also being expressed by their normal counterparts.

The failure of animal models to predict the toxic side effects of a drug in humans creates serious problems. The roughly 80 million years of independent evolution that separate us from our rodent cousins have led to substantial differences in metabolism; we may react to certain drugs much differently from mice or rats, or even the more closely related Old World monkeys, which may eventually be exposed to a candidate drug in order to obtain a slightly more accurate prediction of toxicities in humans. If a drug passes these various pre-clinical tests without raising too many warning flags, it may be promoted to a candidate for testing in humans.

Glossary

xenograft
: A normal or neoplastic tissue derived from one species that has been implanted into a host animal from another species.

autochthonous
: (1) Of native origin. (2) Referring to a tumor that arises within an organism (rather than from implanted cells or tumor fragments).

surrogate marker
: A measurable parameter, often a diagnostic parameter, that serves to indicate the behavior of another process or agent whose behavior it parallels and reflects.

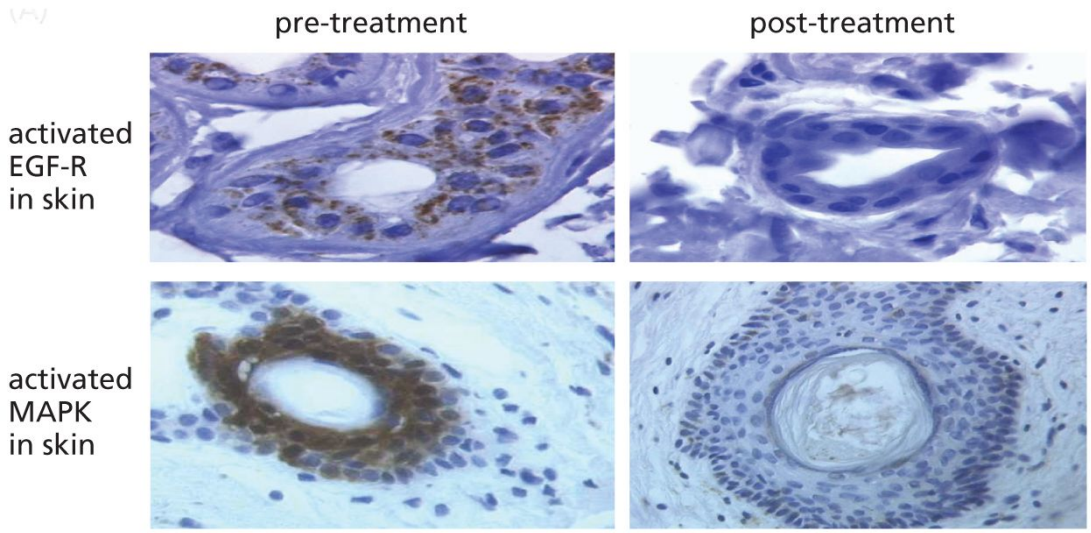
17.9 Promising candidate drugs are subjected to rigorous clinical tests in Phase I trials in humans

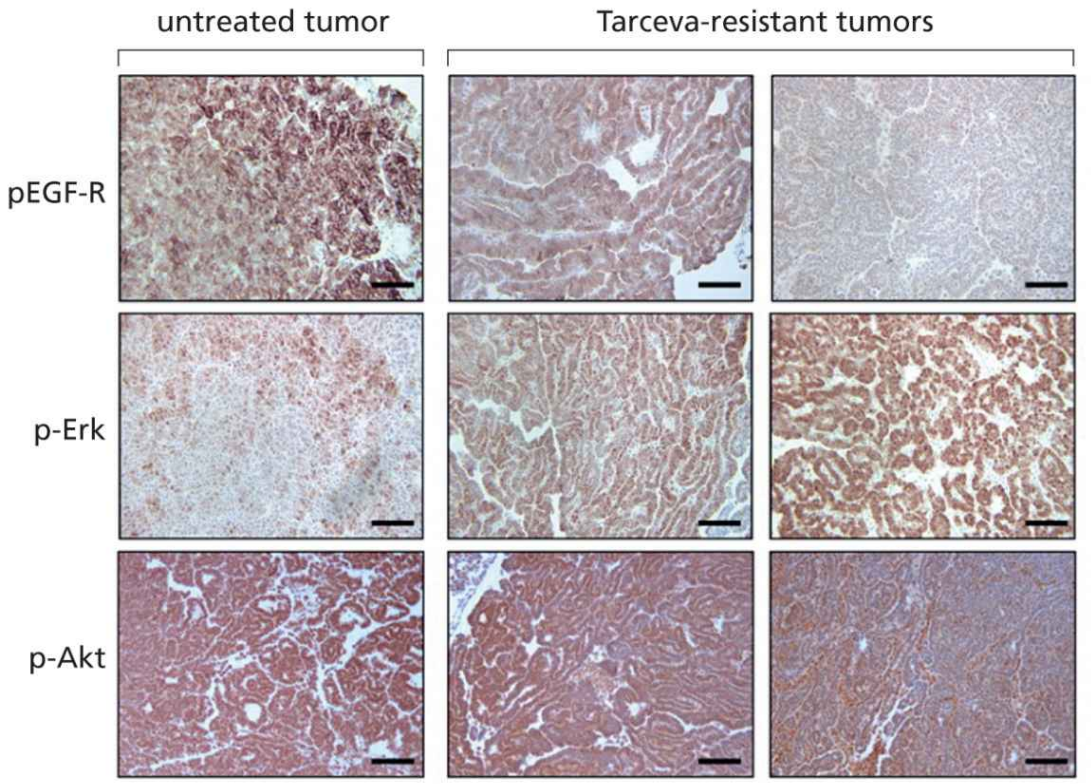
The discussions above explain why the first true tests of a drug's tolerability usually come in initial patient exposures, which are termed Phase I trials in the United States. Here, candidate drugs are tested at various doses, including the presumed therapeutic doses, to gauge toxic side effects rather than drug efficacy. The usual practice is to begin these trials at drug dosages that are likely to be far below the level of any overt toxicity (for example, one-tenth the drug concentration that created toxicity in laboratory animals) and then, in a series of patients, increase the dosages incrementally until drug levels are reached that begin to induce unacceptable toxicities. This "dose escalation" yields a value—the maximum tolerated dose (MTD)—that is then used to guide further treatment protocols. Certain side effects, such as a skin rash or transient nausea, may be tolerable and not scuttle further drug development, whereas others, such as massive diarrhea or bone marrow depletion, may be so burdensome or life-threatening that they cause rapid abandonment of all further development of a drug.

During these Phase I trials, pharmacokinetics measurements, like those made previously in animals, will also be taken in order to ascertain whether the drug is reaching tumor cells at a sufficient concentration and for an extended period of time. Still, these PK measurements give no indication whether or not the cancer cells are responding in any way—the property of pharmacodynamics described earlier. For example, in **Figure 17.24**, we see the PD responses to treatments with EGF receptor antagonists (in this case both a monoclonal antibody and a low–molecular-weight tyrosine kinase inhibitor). To obtain some measure of the effects of therapies on the EGF-R in patients' tumors, the oncologists used, as a surrogate marker, the EGF-R of patients' biopsied skin cells, which were far more easily monitored.



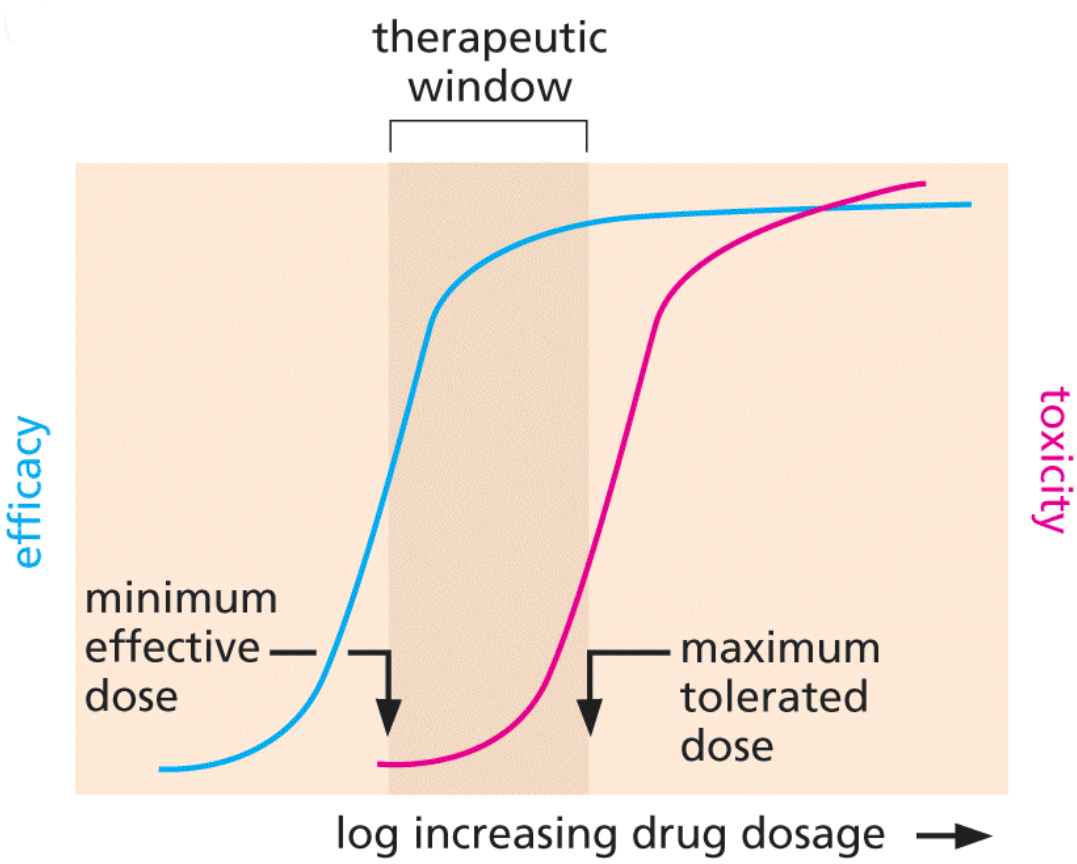
A series of four histology images. When there is activated E G F R in the skin, the pre-treatment image shows scattered brown cells amongst other purple cells. Post-treatment there are no brown cells. When there is activated M A P K in the skin, the pretreatment image shows a ring of brown cells amongst other scattered purple cells. Post-treatment there are no brown cells.

(A)



A series of nine histology images. In an untreated tumor, the p E G F R staining results in dark coloration of cells. The Tarceva resistant tumor images have lighter pink cells. In an untreated tumor, the p E R K staining results in some light pink coloration of cells. The Tarceva resistant tumor images have darker brown cells. In an untreated tumor, the p A k t staining results in a reddish coloration of cells. The Tarceva resistant tumor images have similar colored cells.

(B)



A line graph shows the therapeutic window is between the minimum effective dose and the maximum tolerated dose. On the x axis is increasing drug dosage on the log scale. There are two similar S shaped curves. The efficacy curve is shifted to the right of the toxicity curve. The space between the curves is the therapeutic window.

(C)

Figure 17.24 Measurements of pharmacodynamics and determination of the therapeutic window The extent of inhibition of the EGF-R in a tumor can, in

principle, be gauged by measuring effects of drug treatment on the EGF-R in the skin; the latter is readily assessed through small skin biopsies. In the cases illustrated here, patients were suffering from a variety of tumors, including carcinomas of the ovary, lung, colon, and prostate and head-and-neck cancers. (A) Shown here are the effects of treating a cancer patient with Iressa, a low–molecular-weight EGF-R tyrosine kinase inhibitor (see, as an example, Figure 17.17). The upper panels show immunohistochemistry using an antibody against phospho-EGF-R (*brown*), i.e., the activated form of the receptor. The lower panels used an antibody against phospho-MAPK, the activated form of this downstream kinase (see Figure 6.9A). Both measurements depended on the normally intense mitogenic signaling occurring in hair follicle keratinocytes. (B) The effects of Tarceva, another low–molecular-weight EGF-R tyrosine kinase inhibitor, gauged by immunohistochemical staining of a mouse lung adenocarcinoma. In this case, long-term treatment resulted in a reduction in the overall level of phosphorylated EGF-R (*brown, upper row*). The level of phosphorylated Erk and Akt/PKB (*brown; lower rows*) was, however, elevated in tumor cells that survive Tarceva treatment, suggesting that tumors that escape EGFR inhibition can find alternative mechanisms to activate pathways downstream of active EGFR. (C) Measurements of pharmacodynamics such as these, taken together with studies of pharmacokinetics and toxicity, define the therapeutic window in which a drug should be given—the range of concentrations that are efficacious without creating an unacceptable level of toxic side effects. (A, top from J. Albanell et al., *J. Clin. Oncol*. 20:110-124, 2002. With permission from American Society of Clinical Oncology; bottom from J. Albanell, F., Rojo, and J. Baselga, *Semin. Oncol*. 28:56-66, 2001. With permission from Elsevier. B, Katerina Politi, Pang-Dian Fan, Ronglai Shen, Maureen Zakowski, Harold Varmus; Erlotinib resistance in mouse models of epidermal growth factor receptor-induced lung adenocarcinoma. Dis Model Mech 14 January 2010; 3 (1-2): 111–119. With permission of the Company of Biologists.)

As seen in Figure 17.24A, patient exposure to an EGF-R tyrosine kinase inhibitor resulted in a strong suppression of EGF-R signaling in the skin. In addition, the activity of MAP kinase, which functions as an important downstream transducer of EGF-R signaling (see Section 6.5), was also suppressed, indicating successful inhibition of downstream mitogenic signaling.

Similar results were observed in mouse lung tumors following treatment with Tarceva, a low–molecular-weight EGF-R tyrosine kinase inhibitor (Figure 17.24B). PD measurements like these provide reassurance that the administered treatment is reaching its intended target at concentrations that suffice to shut down much of the target's activity. Interestingly, a number of the signal-transducing proteins operating downstream of the EGF-R, including Erk and Akt/PKB, were expressed at equal or

higher levels in surviving tumor cells indicating that the tumor cells had acquired alternative means for activating these signaling molecules. Hence, PD measurements ensure that one precondition of therapeutic success—delivery of the therapeutic agent to the targeted cells and molecules—has been satisfied, but do not, on their own, guarantee that the therapy will succeed, as other factors may thwart it.

When taken together, the measurements of maximum tolerated dose (MTD), pharmacokinetics (PK), and pharmacodynamics (PD) define the therapeutic window—the range of concentrations that are higher than that needed to elicit a desired therapeutic effect and lower than the maximum tolerated dose (see Figure 17.24C). Ideally, a therapeutic window of a drug should be broad, so as to allow clinicians some flexibility in administering the drug, adjusting dosage to the patient and the condition being treated. As the therapeutic window narrows, the likelihood that a candidate drug will prove clinically useful diminishes.

Occasionally, Phase I clinical trials, which are usually undertaken with very small groups of patient volunteers who have failed other available therapies, may reveal some favorable responses in terms of tumor regression or halting of further tumor growth, doing so at acceptably low levels of toxicity. However, even if there are hints of clinical efficacy, the positive results observed in Phase I trials are never statistically significant and thus not regarded as definitive. Instead, these trials are really undertaken to discover unanticipated toxicities and tolerable levels of drug dosage.

OceanofPDF.com

Glossary

maximum tolerated dose
: The dosage of an administered drug above which a patient suffers unacceptable levels of toxic side effects.

therapeutic window
: Range of concentrations of a drug that are higher than that needed to elicit a therapeutic effect and lower than the maximum tolerated dose. *Also termed* **therapeutic range**.

OceanofPDF.com

17.10 Phase II and III trials provide credible indications of clinical efficacy

Acceptably low levels of toxicity in a Phase I trial will encourage testing a candidate drug's efficacy in a Phase II trial, in which larger groups of cancer patients are involved. Now, for the first time, critical decisions must be made about the indications for enlisting specific patients in the trial—that is, which type of tumor or what stage of tumor progression will justify enrolling patients in such a trial?

Sometimes the clinical indications are obvious. For example, an agent targeted against the Bcr-Abl oncoprotein should be tested in patients diagnosed with chronic myelogenous leukemia (CML). A drug directed against the HER2/neu receptor should be tested in the approximately 30% of breast cancer patients whose tumor cells overexpress this protein. An inhibitor of Raf kinases can be tried in patients with advanced melanomas, in which the B-Raf kinase molecule is often (~60% of cases) mutant and constitutively activated (see Section 17.17).

But more often than not, the choice of indications and clinical response to these indications is neither entirely rational nor optimal. Which class of cancer patients should be treated, for example, with a drug that acts as a general inducer of apoptosis in many types of cancer cells? How should a drug directed against the anti-apoptotic Akt/PKB kinase be used in the clinic? Will an anti-EGF receptor drug prove useful in all carcinomas that express elevated levels of this receptor protein or only a select subset (**Supplementary Sidebar 17.9**)? Significant help here may come from consulting the Cancer Dependency Map (DepMap), which presents a compendium of dependencies of various tumor types on the ongoing functioning of a variety of known, well-characterized signaling proteins. Information obtained from approaches like the DepMap may demarcate sets of tumors that are particularly susceptible to drugs targeting specific signaling pathways. However, as we will see later in this chapter, certain types of cancer that would never be identified by genetics or molecular biology as attractive targets for drug treatment turn out, on occasion, to be highly susceptible to certain drugs under development. In these cases, the therapeutic utility of such drugs is discovered only by chance.

(Given the arbitrary ways in which tumor indications are chosen in many Phase II trials, we can wonder how many truly useful candidate drugs have been discarded in the past, simply because good luck did not favor them in the design of these trials. Thus, it may well be that a drug has the potential to elicit truly spectacular responses when used to treat gastric carcinomas but this effect is never realized, if it is tested in Phase II trials for its effects on pancreatic or lung carcinomas, where it fails to show any useful effects and is therefore dropped entirely from further development and clinical testing.)

If Phase II trials yield clear signs of efficacy for treating certain types of cancer with a candidate drug, Phase III trials, undertaken in far larger patient populations, will be launched. These trials are very costly but are ultimately critical, if only because they may show, for the first time, whether any clinical responses ascribed to a drug are statistically significant. The results of these trials usually become compelling only if control experiments are performed by treating equally large populations of patients with another therapy in parallel, usually one that is already licensed and in widespread use. Importantly, the licensing of a candidate drug for a specific disease indication (in the United States by the Food and Drug Administration, FDA; in the European Union by the European Medicines Agency, EMA) usually depends on whether it yields a therapeutic benefit that is measurably greater than the existing standard of care (**Sidebar 17.12**).

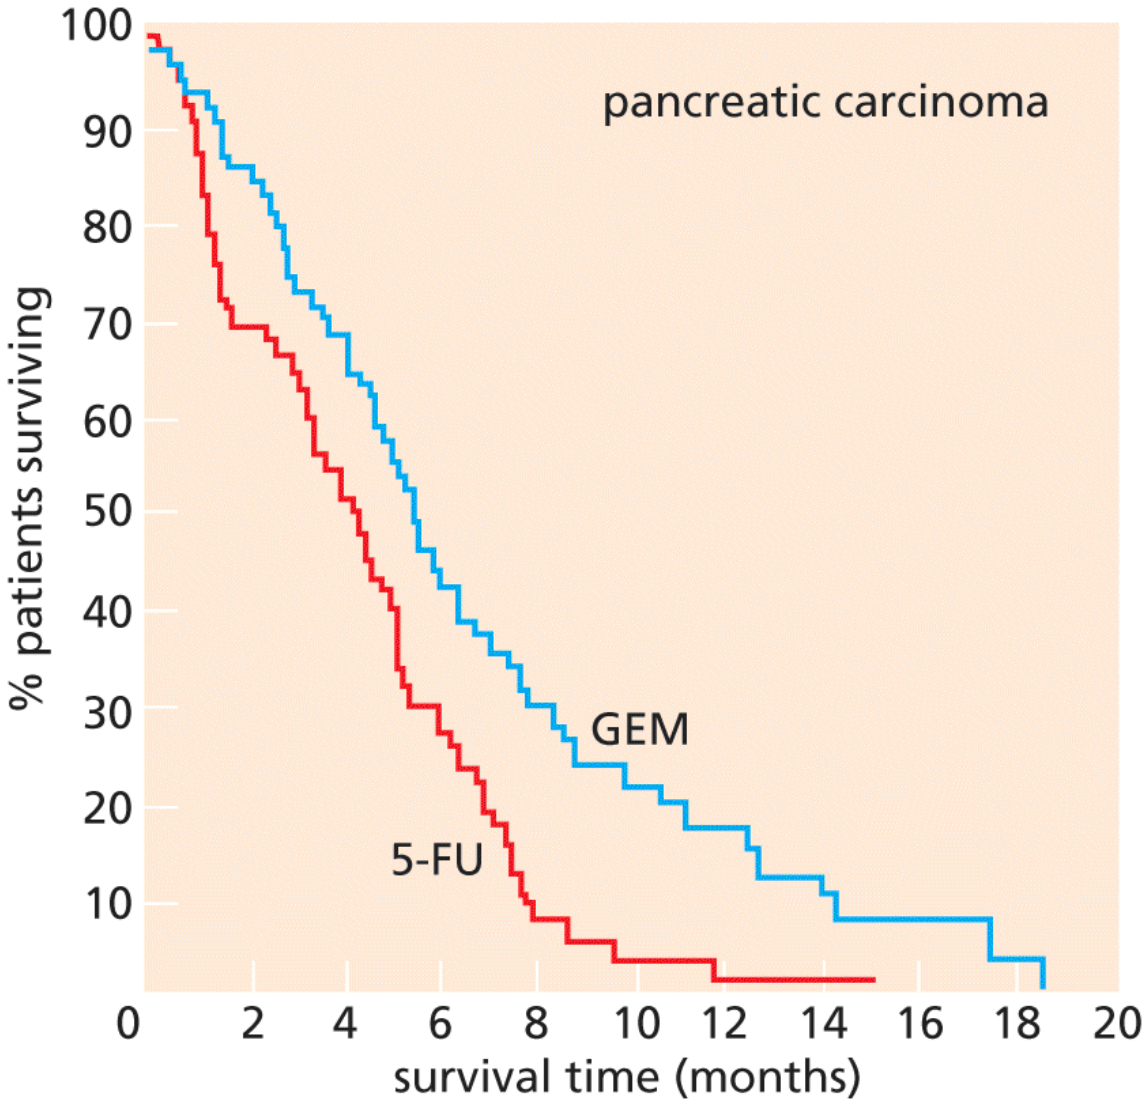
Sidebar 17.12 When do we decide that a drug works?

It is worth considering how one evaluates success of a given therapy in the context of a clinical trial. Certainly the most relevant and compelling metric is whether patients treated with a new agent show increased overall survival relative to those treated with a standard-of-care therapy. However, in many cases, drug efficacy is assessed as the “objective response” of the tumor, itself, to treatment. Alternatively, one can assess the “time to tumor progression” after treatment. Both “objective response” and “time to tumor progression” seek to use changes in tumor size or number as an endpoint upon which efficacy conclusions can be inferred. However, both endpoints are only useful if they are based on widely agreed upon and commonly applied standards. The RECIST (or Response Evaluation Criteria In Solid Tumors) criteria provide general guidelines for how these endpoints are determined. These criteria, which have been periodically updated based on patient response and outcome data and advancing tumor imaging modalities, define a set of four possible outcomes for tumors of a certain

minimum size (at least 10 mm) following treatment. There can be a complete response (CR), in which all tumors shrink below the 10 mm minimum size; a partial response (PR), in which all tumors show at least a 30% decrease in size; progressive disease (PD), in which tumors show at least a 20% increase in size; and stable disease (SD), in which tumors do not show a sufficient volume change to be placed in the PR or PD categories. These criteria have been very useful in comparing the potential efficacy of distinct therapies across broad patient populations. However, these criteria also have significant limitations. Most notably, tumor size changes following treatment correlate but are not necessarily linked with patient outcome. Thus, drugs that elicit a PR may not extend overall survival.

Patients in Phase III trials of anti-cancer agents usually have gone through previous rounds of chemotherapy with various types of cytotoxic agents, each ending with a relapse and the appearance of tumors that are refractory to the already-applied therapy. Moreover, these tumors are often highly aggressive. This patient profile helps to explain why the bar is not set too high for FDA approval of a new drug or drug combination because the drugs in Phase III trials are dispatched to attack the most difficult-to-treat types of cancer. Thus, improvements in patient quality of life or temporary shrinkage of a tumor may suffice even without improvement in long-term survival.

One illustration of this comes from a current treatment for pancreatic cancer. This disease is an extreme example, to be sure, in that the five-year survival rate of this disease (from the time of initial diagnosis) is consistently less than 5%. Gemcitabine (difluorodeoxycytidine; see Figure 17.6), which is widely employed as a therapy for pancreatic carcinoma, received initial FDA approval because in some patients it resulted in an improvement in symptoms, weight gain, and a temporary stabilization in tumor growth, although it offered only a modest increase in survival time (from the time of diagnosis): patients treated with gemcitabine had a median survival time of 5.65 months compared with those given the existing standard of care—5-fluorouracil (5-FU), which afforded them a 4.41-month median survival time (**Figure 17.25**). This and similar anecdotes reveal how desperate is the need for truly effective means of treating solid tumors.



A line graph shows the survival of pancreatic carcinoma patients that were treated with 5 F U or G E M. By 8 months, less than 10 percent of the patients treated with 5 F U were surviving. None survived past 15 months. By 14 months, less than 10 percent of the patients treated with G E M were surviving. None survived past 19 months.

Figure 17.25 Gemcitabine as a treatment for pancreatic cancer This Kaplan–Meier plot illustrates the high mortality exacted by pancreatic cancer. Patients treated with gemcitabine (GEM; see Figure 17.7) lived slightly longer than those treated with 5-fluorouracil (5-FU)—the standard treatment in the 1990s. Both agents are pyrimidine derivatives whose cytotoxicity derives from their ability to inhibit DNA synthesis, in part through misincorporation into the DNA. (5-FU also interferes with pyrimidine

biosynthesis.) As is apparent, gemcitabine treatment offered only a modest increase in patient survival in this study reported in 1997, but this nevertheless sufficed to allow its approval by the U.S. Food and Drug Administration. (From H.A. Burris III et al., *J. Clin. Oncol*. 15:2403–2413, 1997. With permission from American Society of Clinical Oncology.)

Nonetheless, even with these relatively modest regulatory requirements, the other obstacles in drug development described here keep the current success rate for anti-cancer drug development extremely low. Perhaps one drug in a hundred advances all the way through the drug development "pipeline" from initial *in vitro* testing through a Phase III trial that culminates in some clear improvement in patient outcome and licensing by the FDA. (After licensing has occurred, a Phase IV trial may be conducted to determine the efficacy of drug treatment over an extended period of time, how certain subgroups of patients respond to the drug, and whether concerns about a drug's safety eventually emerge from its use in very large patient populations.)

OceanofPDF.com

Glossary

indication
: A clinically observed trait or property that represents a valid reason for the making of a certain diagnosis or use of a certain therapy.

standard of care
: The therapeutic agent or protocol that is widely accepted in the treatment of disease and often serves as the reference against which candidate novel treatments are measured.

17.11 Tumors often develop resistance to initially effective therapy

A complication that dogs all anti-cancer drugs is illustrated by the behavior of *HER2/neu* transgenic mice, in which the mutant, oncogenic transgene has been programmed to induce mammary tumors on a predictable schedule and can be shut down thereafter. Although transgene-induced primary breast tumors and metastases all collapsed when the *HER2/neu* transgene was shut down, new tumors recurred in most of these mice between 1 and 9 months later. These tumors clearly represented variants of the initially observed ones that had developed alternative means of propelling their growth—that is, had become independent of *HER2/neu* oncogene expression.

As we saw in Chapter 12, the unstable, mutable genomes of cancer cells continually generate new alleles and novel genetic configurations (see Section 12.15). Evolving cancer cells can pick and choose among these genetic variations, searching for combinations that improve their ability to survive and proliferate. In this *HER2/neu* example, the relatively small number of cancer cells that survived oncogene shutdown seem to have spent months thereafter trolling for newly arising oncogenes (or other cancer-causing alleles) in their genomes that might enable them to re-launch their program of aggressive proliferation. The rare cells that happened to acquire such advantageous alleles or epigenetic states then began clonal expansions that led to relapsing tumors.

A similar dynamic complicates almost all types of human cancer therapies, where initial clinical successes in reducing tumor cell populations are usually followed by the re-emergence in patients of tumor cell populations that have, through one means or another, developed resistance to the treatment (see Table 17.5). Much of this acquired resistance is attributable to the genetic and therefore phenotypic plasticity of cancer cell populations. Importantly, much of this “acquired” resistance may derive from variants that already existed within a tumor at the time the therapy was initiated.

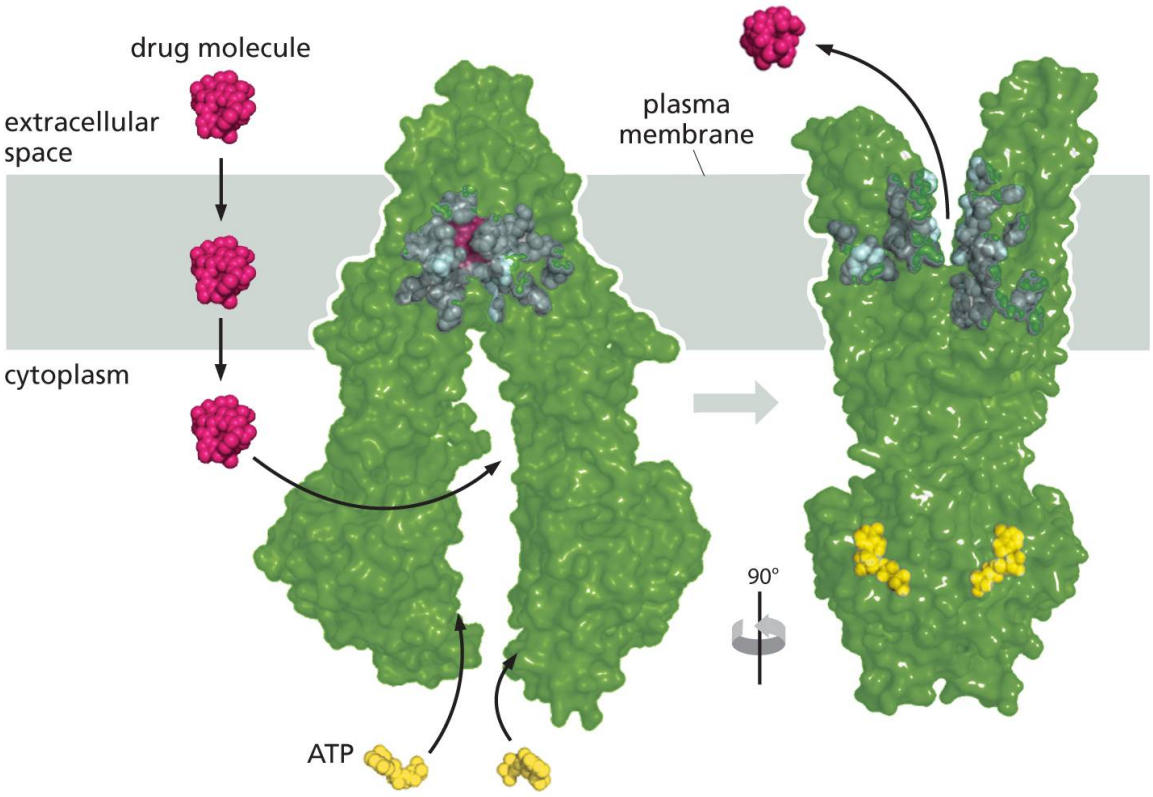
The acquired mechanisms of drug resistance are quite variable and illustrate the ingenuity of cancer cells (see Table 17.5). Perhaps the most intuitive of all

resistance mechanisms are alterations that block drug–target interactions. These alterations include mutations that change the structures of targeted proteins and directly prevent drug binding. They can also confer a decreased ability to import drug molecules through the plasma membrane or an acquired ability to pump out drug molecules through this membrane.

Other resistance mechanisms depend on the acquired ability to metabolize drug molecules, converting them to inactive products, in some cases using the same classes of enzymes that normally operate to detoxify toxic compounds that have entered the cell (see Section 12.5). Cells may also neutralize components of their apoptotic machinery or may acquire an increased ability to repair DNA molecules damaged by chemotherapeutics or radiation. Finally, tumor cells can undergo state changes—that is, transitions from one phenotypic state to another—that result in a decreased dependence on a particular drug target and perhaps, an acquired dependence on another. Sometimes multiple alternative resistance mechanisms can arise in response to a given therapy and multiple resistance-mediating alterations may operate concomitantly within a given tumor.

These behaviors represent a general challenge to all types of anti-tumor therapy, as discussed earlier in Section 17.2. The response to such acquired resistance was the development of multi-drug therapies. However, even these multi-drug therapy strategies are often foiled by cancer cells. For example, as mentioned, lymphomas treated with combination chemotherapy frequently relapse. Moreover, despite 60 years of clinical experience with lymphoma chemotherapy, the basic mechanisms of drug relapse in this context remain unclear and obvious resistance mutations have not been identified.

In recent years we have learned much about how multi-drug resistance can be achieved at the molecular level. For example, high-level expression of the *MDR1* gene, which encodes a normal transmembrane drug efflux pump, enables cancer cells to efficiently excrete a variety of chemically unrelated drugs, thereby lowering intracellular drug concentrations to subtoxic levels (**Figure 17.26**). Similarly, inactivation of certain parts of the apoptotic machinery (see Table 17.5) may also confer concomitant resistance to a number of distinct cytotoxic agents. However, whether these processes represent major mediators of multi-drug resistance in cancer patients remains unclear.



Space filling models show a P glycoprotein removing a drug molecule from a cell. The P glycoprotein is embedded in the cell membrane. A drug molecule enters the cytoplasm from the extracellular space through the cell membrane. The drug molecule binds to the cytoplasmic side of the P glycoprotein, and A T P enters, resulting in a change in conformation of the P glycoprotein. The drug molecule is ejected into the extracellular space.

Figure 17.26 Multi-drug resistance and the P-glycoprotein The MDR1 gene encodes P-glycoprotein (P-gp, *green*), a protein that is often present at elevated levels in cancer cells being treated with various types of chemotherapy. A structural model of P-gp is shown here. It is a 170-kD ATP-dependent transmembrane protein that can pump out of cells a wide variety of molecules with molecular weights ranging from 330 up to 4000. Its elevated expression is often associated with and likely causes multi-drug resistance. It is a member of a large family of mammalian ABC (ATP-binding cassette) transporter molecules, of which 49 have been discovered. As shown, a substrate such as a chemotherapeutic drug (*magenta*) enters the cell and is bound by the cytoplasmic domains of P-gp (*left*). In response to this binding and the binding of ATP molecules (*yellow*), the P-gp undergoes a profound conformational shift that collapses its cytoplasmic substrate-binding domain

and opens its domain facing the extracellular space (*right*), resulting in the extrusion of the drug molecule from the cell. The drug-binding pocket is shown in *cyan*. The right P-gp molecule has been rotated 90 degrees to better illustrate the stereochemistry of the drug-extrusion step. (From S.G. Aller et al., *Science* 323:1718–1722, 2009. With permission from AAAS.)

The advent of molecularly targeted agents, as discussed in the following sections, has highlighted the tremendous challenge of acquired drug resistance. Tumors almost invariably relapse with resistance-causing alterations after treatment with targeted therapy. This grim clinical reality has led to widespread consensus among drug developers: monotherapies involving either low–molecular-weight drugs or biological molecules are unlikely to cure most types of cancer, and effective multi-agent therapies must be devised if definitive, durable clinical responses are to be achieved in the future.

With these considerations in mind, we will read about a series of illustrative anecdotes in the ensuing sections. Each concerns a type of drug and its targets within cancer cells. The stories are arranged in an order, beginning with a well-established therapy and ending with a speculative one that holds great promise but is still far from clinical validation. In some cases, the specific therapy was inspired by discoveries of malfunctioning proteins within cancer cells; these discoveries allowed drug development to be pursued logically and methodically. In other cases, strokes of good luck or intuitive leaps enabled the development of highly active compounds. Inevitably, these anecdotes represent arbitrary choices and draw from a vast pool of agents currently under investigation or development. They represent the forerunners of many such drugs that will surely be developed and licensed for clinical use in the years to come.

OceanofPDF.com

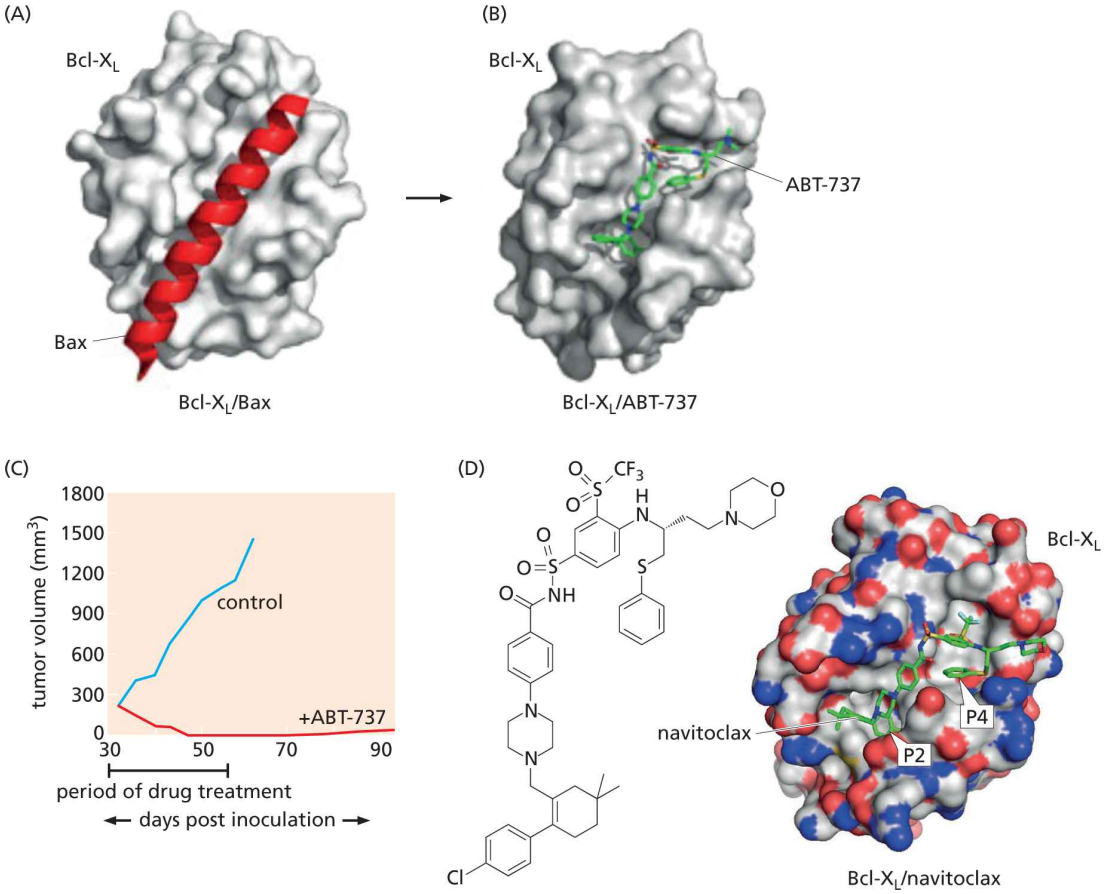
17.12 Targeting Bcl-2 to induce cell death

Arguably the most effective way to treat a tumor is to induce death in its constituent neoplastic cells, specifically to activate the apoptotic cell death program described in detail in Chapter 9. As revealed there, decisions of life versus death in the cell often depend on the functional balances between countervailing pro- and anti-apoptotic proteins, most directly depicted in Figure 9.25C. As described there, these mutually antagonistic proteins are all members of the Bcl-2 family, and they all operate in one or another way to open outer mitochondrial membrane pores (pro-apoptotic) or to hold these pores shut (anti-apoptotic). The presence of Bcl-2 translocations and deregulated expression in B-cell malignancies, coupled with an understanding of anti-apoptotic Bcl-2 function at the mitochondrial outer membrane, suggested that an ongoing block to apoptosis may represent a core dependency in certain cancers.

As was discussed, this hypothesis was tested in mouse models in which Myc and Bcl-2 coordinately promoted B-cell lymphoma development (Section 9.13). Genetic deletion of the Bcl-2 transgene expression in these tumors led to rapid apoptosis and tumor regression. Thus, not only could Bcl-2 promote tumor development, but it was also necessary for ongoing tumor maintenance and, consequently, rose to the level of a highly attractive target for anti-cancer drug development. However, a strategy to target Bcl-2 was complicated because it lacked any targetable catalytic site or drug-binding structural pocket. Attempts to use antisense nucleic acids targeting Bcl-2 mRNA were undertaken in the clinic, but these approaches achieved limited overall success.

A key breakthrough toward understanding how to target anti-apoptotic Bcl-2 members came from examining the interaction between BH3-only Bcl-2 family members and their anti-apoptotic targets. The observation that small peptide domains were able to block Bcl-2 interactions with Bax led to the development of short BH3 peptide mimetics that could recapitulate some of the activity of BH3-only proteins (see Figures 9.23 and 9.25). These BH3 peptide mimetics have since become an effective tool for examining the propensity of specific cells to undergo apoptosis in response to diverse stimuli including anti-cancer agents (**Supplementary Sidebar 17.10**). Using a chemical screening approach based on nuclear magnetic resonance, a small molecule BH3 mimetic termed ABT-737 was developed. This molecule represented one of the first anti-cancer agents that was developed based on structural prediction and simulation. Molecules were identified that could recapitulate two distinct binding interfaces of the BH3-only protein Bim bound to the BH2 and BH4 pockets of Bcl-X_L. These two binding fragments were then cleverly linked together to generate the final

ABT-737 molecule (**Figure 17.27A**). ABT-737 bound Bcl-2 and Bcl-X_L with high affinity and showed potent single-agent killing in a range of tumor cell lines and murine tumors (Figure 17.27B).



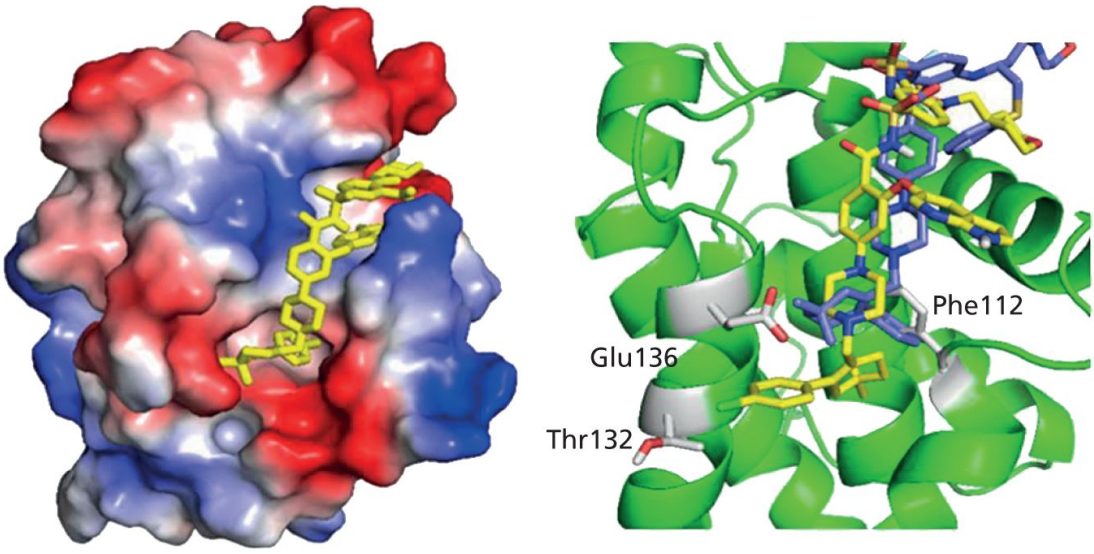
A four part figure about anti-apoptotic B c l 2 family inhibitors. Part A. A space filling model of a B c l X L slash Bax complex. An alpha helix of Bax binds to a groove in the B c l X L protein. Part B. A space filling model of a B c l X L slash A B T 737 complex. A molecule of A B T 737 binds to a groove in the B c l X L protein. Part C. A line graph shows the change in tumor volume in a control and when treated with A B T 737. On the x axis is days post inoculation. The period of drug treatment is from 30 to 55 days. Both tumors start at just under 300 cubic millimeters. The control increases steadily to about 1500 cubic centimeters by day 65. The tumor treated with A B T 737 decreases in size to about 0 cubic millimeters by day 50 and remains close to 0 through day 90. Part D. The molecular structure of navitoclax and a space filling model of navitoclax bound to B c l X L. The molecular structure is complex with several six membered rings. Nitrogen, sulfur, and oxygen groups are integrated throughout the structure. The model shows navitoclax binding with pockets P2 and P4 of a groove in B c l X L.

Figure 17.27 The development of anti-apoptotic Bcl-2-family inhibitors (A) The drug termed ABT-737 was developed using nuclear magnetic resonance (NMR)-based screening, parallel synthesis (a form of combinatorial chemistry), and structure-based design, undertaken to visualize the interacting structures of pro-apoptotic Bcl-2 family members with the anti-apoptotic protein Bcl-X_L. The α-helix of the pro-apoptotic Bax protein (*red helix*; see also Figures 9.23 and 9.25) binds to a groove in Bcl-X_L protein (*white/gray surface*) and inhibits its anti-apoptotic function. (B) This groove is also occupied by ABT-737, a small molecule (*green stick figure*)—specifically designed to mimic and thus compete with this protein–protein interaction. (C) The effects of ABT-737 on the growth of a human small-cell lung carcinoma (SCLC) xenograft are shown in the graph. The black bar indicates the time window during which ABT-737 was applied. (D) An orally bioavailable compound navitoclax (also known as ABT-263, *green*), an inhibitor of the Bcl-2, Bcl-X_L and MCL1 anti-apoptotic proteins, was subsequently generated. Shown is an X-ray co-crystal structure of navitoclax (*green stick figure*) bound to Bcl-X_L (*red, white, blue*) with critical drug-binding pockets indicated as P2 and P4. Because navitoclax inhibits Bcl-X_L, a protein important for blood platelet life span, dose-limiting thrombocytopenia has presented a barrier for expanded clinical use of this agent. (A, from N. Chessum et al., *Prog Med Chem.*54:1–63, 2015. With permission from Elsevier. B, from A. Ashkenazi et al., *Nat. Rev. Drug Discov*. 16:273–284, 2017. With permission from Elsevier. C, from T. Oltersdorf et al., *Nature* 435:677–681, 2005. With permission from Nature. D, A. Ashkenazi et al., *Nat. Rev. Drug Discov.* 16:273–285, 2017. With permission from Nature.)

An orally available version of ABT-737, termed ABT-263 (Figure 17.27C), was subsequently developed and introduced into clinical trials as a monotherapy in patients with chronic lymphocytic leukemia (CLL). Here, as occurs in the context of many clinical trials, the agent produced an unanticipated toxicity. Although effective in eliminating leukemia cells, ABT-263 also demonstrated significant platelet toxicity. The resulting thrombocytopenia (and associated risk of hemorrhages) restricted the ability to introduce larger doses of ABT-263 and limited the overall efficacy of this drug.

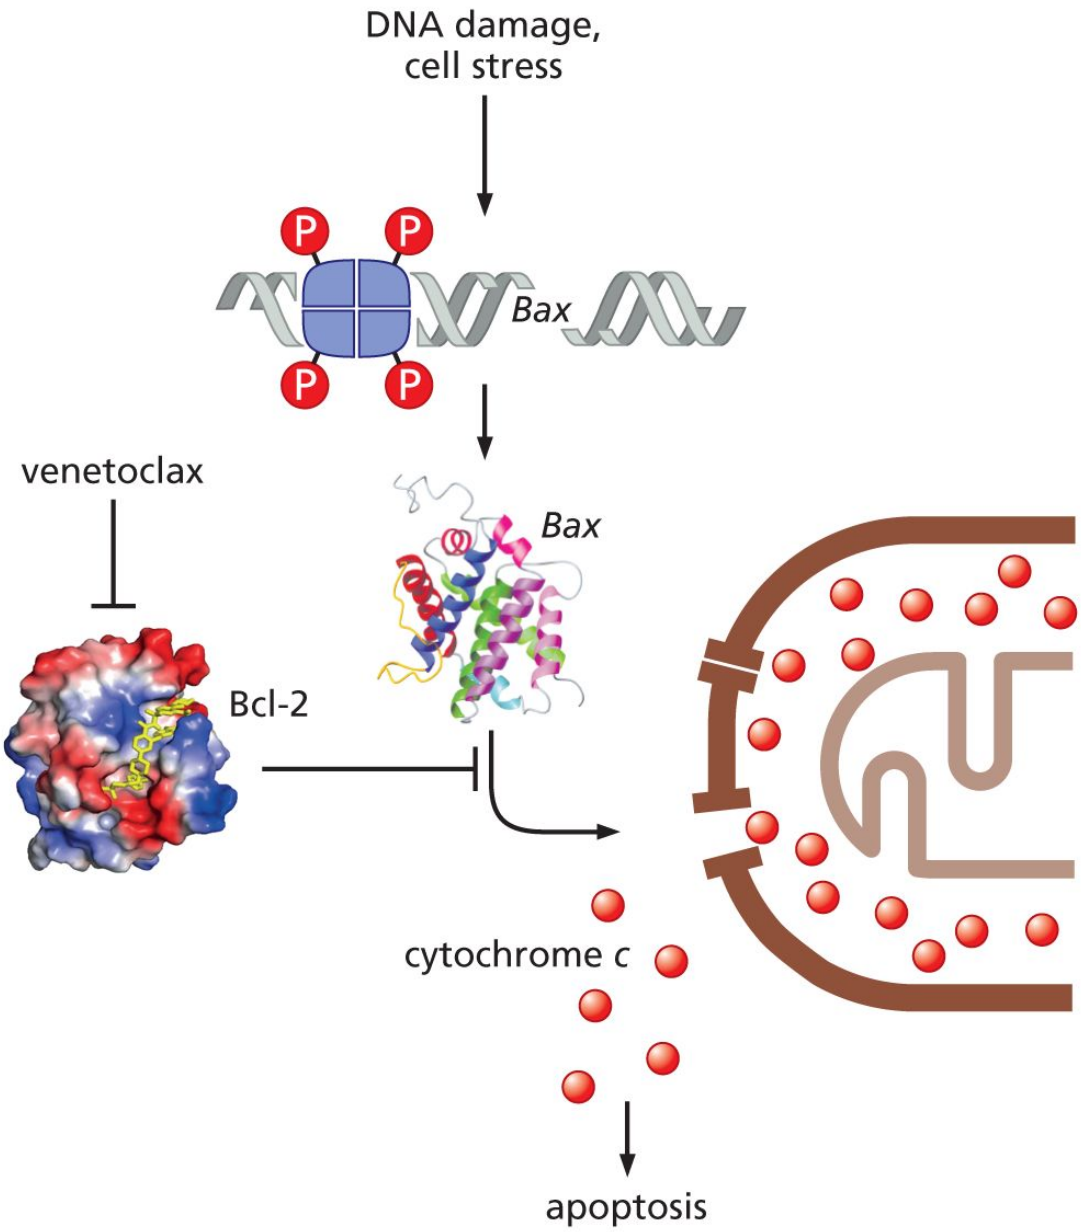
Although this type of setback in a clinical trial represents the end of many drug development programs, a broad understanding of Bcl-2-family protein biology provided a key insight into this toxicity. Specifically, Bcl-X_L was determined to be essential for the survival of platelets and, indeed, ABT-263 was found to target both Bcl-2 (its intended target) and Bcl-X_l. This finding led to further efforts to apply the same approach used previously to formulate ABT-737 in order to generate a Bcl-2

specific inhibitor. The result was the development of ABT-199 (or venetoclax), a selective, orally bioavailable and potent inhibitor of Bcl-2 that lacks significant platelet toxicity (**Figure 17.28A**).



A 3 D model of venetoclax binding to a cleft in B c l 2. A ribbon diagram shows that venetoclax interacts with glutamine 136, threonine 132, and phenylalanine 112.

(A)



A diagram shows the pathways leading to induction of apoptosis. D N A damage and cell stress stimulate the translation of the Bax gene to create the Bax protein. Venetoclax inhibits B c l 2 from inhibiting Bax. Bax stimulates the release of cytochrome c from the mitochondria which leads to apoptosis.

(B)

Figure 17.28 The development of venetoclax Structure-based design was used to generate Bcl-2-selective small molecules, based on the idea that such molecules would maintain anti-tumor activity while avoiding the thrombocytopenia induced by navitoclax (see Figure 17.27). (A) A model of venetoclax (also known as ABT-

199, *yellow*) binding to Bcl-2 (*left*) shows the Bcl-2 electrostatic surface, with positive charges in *blue* and negative charges in *red*. The image compares the interacting residues in Bcl-2 (*green*, *right*), venetoclax (*yellow*), and navitoclax (*blue-purple*). Here, the amino residues Phe112, Thr132, and Glu136 (latter two in *red*, *white*) of Bcl-2 specifically interact with venetoclax, which underlies the specificity of this agent as a Bcl-2 inhibitor. (B) The diagram shows pathways leading to induction of apoptosis. In the absence of p53-dependent induction of BH3-only proteins (notably Bax), Bcl-2 holds mitochondrial outer membrane channels shut, preventing release of cytochrome *c*, and cellular stresses fail to induce cell death; this explains why malignancies like p53-deficient chronic lymphocytic leukemia (CLL) are highly resistant to genotoxic agents. Venetoclax blocks the ability of Bcl-2 to inhibit pro-apoptotic Bax (and Bak, *not shown*) and renders p53-deficient tumor cells vulnerable to cellular stress. Results to date indicate that venetoclax functions most effectively to sensitize cancer cells to the killing effects of FDA-approved cytotoxic drugs. (A, from J. Ramos et al., *Int. J. Mol. Sci.* 20:860–879, 2019. B, adapted from M. Suzuki, R.J. Youle and N. Tjandra, *Cell* 103:645–654, 2000. With permission from Elsevier.)

Venetoclax has achieved clinical success in the treatment of CLLs that lack chromosome 17p, an alteration that most notably results in the loss of p53 expression (Figure 17.28B). Notably, 17p loss does not, per se, sensitize these cancers to Bcl-2 inhibition. Instead, CLLs with 17p loss are highly resistant to existing standard-of-care therapies, making it possible to rapidly identify a subset of patients who would not benefit from existing chemotherapy. As is the case for many cancers, it was the absence of effective alternative treatments that provided the opportunity and impetus to try new approaches.

Soon extensive experimental data showed that overexpressed Bcl-2 could promote neoplastic progression in a broad set of hematopoietic cell types, explaining why much of the pre-clinical and clinical efforts to explore the clinical utility of venetoclax has focused on blood cancers. These treatment studies included patients with acute myelogenous leukemia (AML), a cancer that is currently treated with conventional combination chemotherapy and has a generally poor prognosis. Venetoclax, in combination with other agents, has shown significant clinical efficacy in AML patients who cannot tolerate the toxicity associated with high-dose chemotherapy. Here again, it was the inability to treat patients with a standard-of-care therapy that provided the opportunity and incentive to test a new agent. Although it remains to be seen if this treatment can supplant standard-of-care regimens in this disease, the introduction of an alternative to toxic combination-chemotherapy represents an important development for the treatment of AML.

Glossary

nuclear magnetic resonance
: Analytical procedure for determining molecular structures and interactions in which molecules are placed under strong magnetic fields and the influence of radio frequency waves; the frequencies at which the atoms within a molecule resonate yields information on the molecular interactions of individual atoms and, in turn, the overall structure of a complex molecule.

monotherapy
: A therapy in which only a single drug or treatment is used at one time.

thrombocytopenia
: A deficiency of platelets in the circulation.

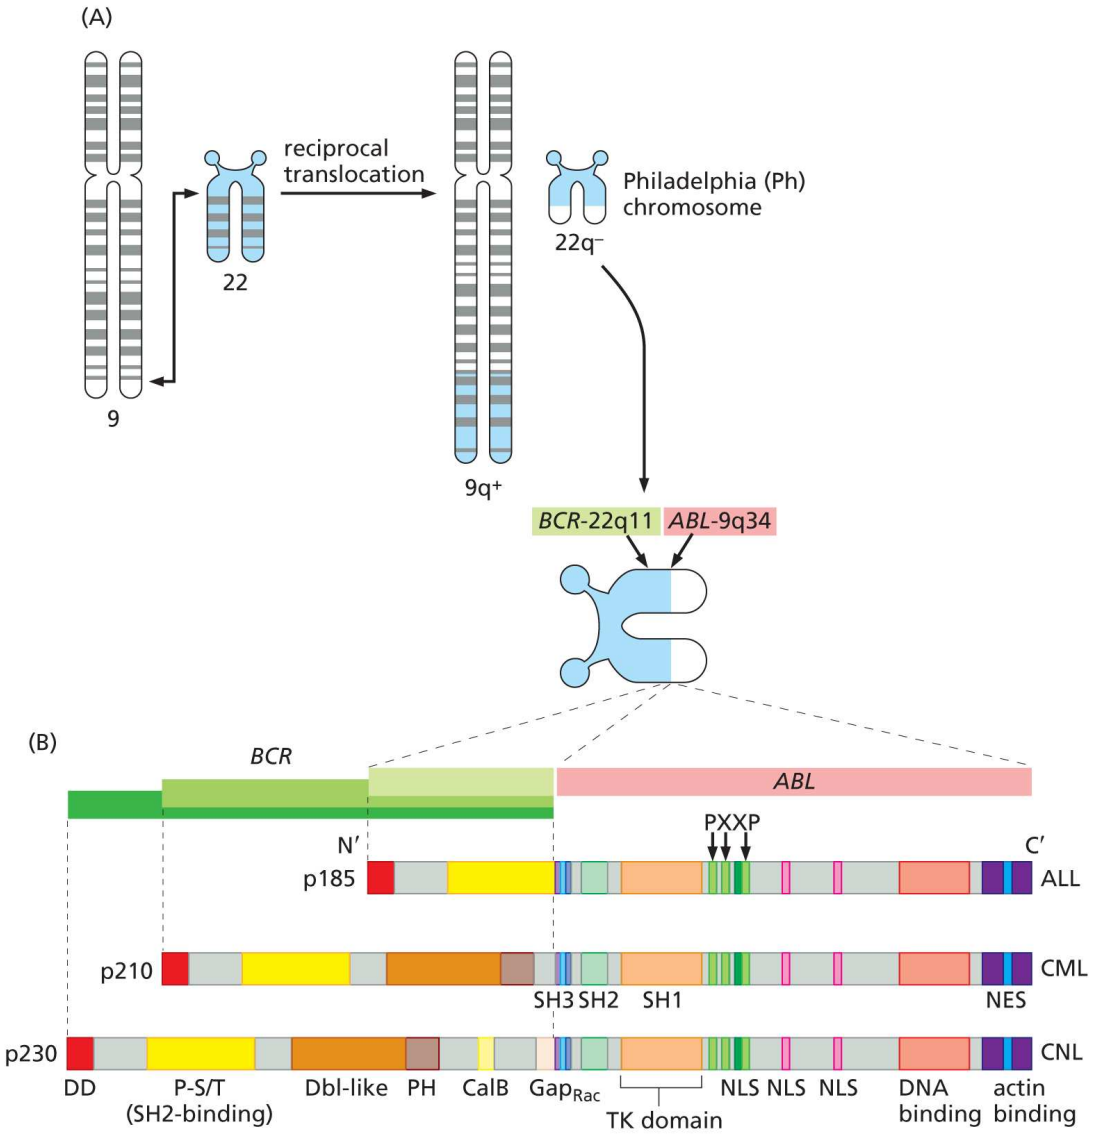
17.13 Gleevec paved the way for the development of many other highly targeted compounds

In the previous sections, we made repeated reference to the Bcr-Abl oncoprotein and to experimental strategies for antagonizing it. Now, we backtrack and review the history of how the Bcr-Abl oncoprotein was discovered and validated as an attractive drug target and finally used as an object of rational drug design. This story is valuable, if only because it illustrates vividly the long course through which drug development passes from initial discovery at the laboratory bench to the oncology clinic.

This particular story begins in 1914, when the German cytologist Theodor Boveri proposed that chromosomal defects might cause a cell to proliferate abnormally, resulting ultimately in the formation of some type of cancer. Almost half a century passed before Boveri's idea received some validation. In 1960, two cytologists working in Philadelphia noted that an abnormal, unusually small Chromosome 22 was characteristically present in the great majority of cells of chronic myelogenous leukemia (CML); since that time, it has been called the Philadelphia chromosome or simply Ph. It took another dozen years before a researcher in Chicago demonstrated that a reciprocal translocation between Chromosomes 9 and 22 was responsible for creating the Ph chromosome (see Section 4.5). (A larger chunk of Chromosome 22 is donated to the tip of Chromosome 9 than is received from this chromosome, leaving the already-tiny Chromosome 22 even more diminished in size; this remnant of 22 plus the small translocated segment constitutes the Ph chromosome; **Figure 17.29A**). The chromosomal aberration—clearly representing a somatic mutation—was proposed as a potential cause of this malignancy. As mentioned earlier, we now know that this particular translocation is present in more than 95% of cases of CML.



A two part figure shows the origin and structure of the B c r A b l protein. Part A. An illustration shows the formation of the Philadelphia, or P h, chromosome. When reciprocal translocation occurs between chromosomes 9 and 22, it forms 9 q plus, which is longer than 9, and 22 q minus, which is shorter than 22. 22 q minus is the Philadelphia chromosome, and the resulting section around the breakpoint boundary is a fusion of B C R 22 q 11 and A B L 9 q 34. Part B. A diagram shows the different breakpoints in the chromosome and the proteins that they form. The A b l side is always present and consists of the following domains, S H 3, S H 2, S H 1, which is the T K domain, P X X P, the N L S domains, a D N A binding domain, an actin binding domain, and N E S. The B C R side can be different length,s all which contain the D D domain and the S H 2 binding domain. In the p 185 protein, nothing else is present. The p 210 protein also contains D b l like and P H domains. The p 230 protein also contains Cal B and Gap sub Rac domains.

Figure 17.29 Origin and structure of the Bcr-Abl protein (A) More than 95% of cases of chronic myelogenous leukemia (CML) exhibit the Philadelphia chromosome, which results from a reciprocal translocation between Chromosomes 9 and 22. The q34 region of Chromosome 9 carrying most of the *ABL* gene is transferred to the q11 region of Chromosome 22, replacing a larger segment of Chromosome 22 that is translocated reciprocally to Chromosome 9. The net result is a truncated Chromosome 22 (i.e., $22q^{-}$), often termed the Philadelphia chromosome (Ph), and a fusion of the 5′ portion of the *ABL* gene with a 3′-proximal portion of the *BCR* gene, which normally resides at 22q11. (B) Depending on the precise location of the breakpoint in *BCR*, three distinct Bcr-Abl fusion proteins may be formed; these are found in ALL (acute lymphoblastic leukemia), CML, and CNL (chronic neutrophilic leukemia). Each of these *BCR-ABL* fusion genes encodes a multidomain (and thus multifunctional) protein. (From A.S. Advani and A.M. Pendergast, *Leuk. Res*. 26:713–720, 2002. With permission from Elsevier.)

The genes that were fused through this translocation remained unknown until 1982, when molecular biologists discovered that *ABL*, the human homolog of the mouse c-*abl* proto-oncogene (see Tables 4.1 and 4.5), participates directly in these chromosomal translocations, becoming fused with a second, still unknown gene. The breakpoints of this other gene (the chromosomal sites at which it becomes fused to the *ABL* gene) were soon found to be scattered over many kilobases of DNA, yielding the name "**b**reakpoint **c**luster **r**egion" or simply *BCR*. In fact, three distinct fusion proteins arise through the inclusion of variously sized Bcr proteins at the N-termini of the fusion proteins, with almost the entire Abl protein at the C-termini (see Figures 4.11 and 17.29B). As indicated in the figure, the different fusion proteins tend to be associated with distinct types of leukemia.

Within two years of its discovery, the Bcr-Abl protein was found to function as a constitutively activated tyrosine kinase. In this respect, it functions like the Abl oncoprotein of Abelson mouse leukemia virus. Like other acutely transforming retroviruses, the genome of this virus carries an oncogene—in this case *abl*—derived from a corresponding proto-oncogene residing in the normal mouse genome (see Section 3.10).

By 1990, a cDNA encoding the Bcr-Abl fusion protein had been introduced into a retrovirus vector, and the resulting virus was then found to induce in mice a leukemia that closely resembled human CML. Like the human disease, this leukemia involved large numbers of fully differentiated granulocytes in the blood. Under certain conditions, the mouse leukemia, like its human counterpart, progressed to a "blast crisis," involving the accumulation of immature cells of the lymphoid or myeloid lineages (see also Sidebar 8.7). These observations in mice represented the first formal

proof that the Bcr-Abl fusion protein operates as the central motive force of leukemogenesis in CML.

Unfortunately, this demonstration of the critical role of Bcr-Abl revealed nothing about the mechanisms by which it functions. The bewildering complexity of Bcr-Abl signaling is indicated by the diverse array of structural and functional domains in the two contributing proteins (see Figures 4.11B and 17.29B). Altogether, the domains of this fusion protein enable it to activate the Ras pathway, the PI3 kinase–Akt/PKB pathway, the Jak–STAT pathway, and transcription factors, including Jun, Myc, and NF-κB. In addition, the Ras-like Rac protein, which regulates activities as diverse as cellular migration, survival, and proliferation, is activated, as are two nonreceptor tyrosine kinases, Hck and Fes. These various associations enable the Bcr-Abl protein to extend its reach into almost all the regulatory circuits governing cell proliferation and survival.

In spite of this complexity, the tyrosine kinase domain of Bcr-Abl was found to be the key element in leukemogenesis. For example, subtle alterations of the Bcr-Abl protein that inactivated its tyrosine kinase catalytic activity led to total loss of its transforming function. In the early 1990s, a research program was begun to develop low–molecular-weight antagonists of the Bcr-Abl tyrosine kinase activity. A drug molecule emerged, termed variously imatinib mesylate, STI-571, Glivec, and Gleevec (see Figure 17.13A), which was able to bind the catalytic cleft of the Bcr-Abl tyrosine kinase. As is the case with all other kinases of this family, the cleft is located between the two major structural lobes of the kinase protein (see Figures 6.6 and 17.13B).

Even though the Abl kinase domain shares roughly 42% amino acid identity with a large number of other tyrosine kinases, the inhibitory effects of Gleevec on Bcr-Abl were found to be relatively specific (see Figure 17.16). Subsequently, four other tyrosine kinases—those belonging to the PDGF (α and β) and Kit receptors as well as the Arg (Abelson-related gene) protein—were also found to be inhibited by Gleevec. Accordingly, this drug, when used at therapeutic concentrations, appears to target only 4 of the 90 or so human tyrosine kinases. Like most other kinase inhibitors, the Gleevec molecule associates directly with the ATP-binding pocket of the Abl kinase domain (see Figure 17.13). Whereas other kinase inhibitors block ATP binding in this cleft, Gleevec works differently: it binds and stabilizes a catalytically inactive conformation of this enzyme (much like the small drug molecule that inhibits the G12C mutant Ras protein; see Section 17.4).

The success with Gleevec encouraged other attempts at creating low–molecular-weight kinase antagonists, which were realized to have certain therapeutic advantages over anti-receptor monoclonal antibodies (**Table 17.7**). In addition, this advance stimulated efforts to make narrowly targeted tyrosine kinase inhibitors, some of which have indeed demonstrated extraordinary specificity. For example, even though the tyrosine

kinase domains of the insulin receptor (IR) and insulin-like growth factor receptor (IGF-1R) are very similar in structure (84% identity in kinase domain residues), a low–molecular-weight inhibitor has been developed that targets preferentially the IGF-1R, doing so at a concentration that is 27-fold lower than that required for it to inhibit the IR.

Table 17.7 Strengths and weaknesses of anti-receptor antibodies versus low–molecular-weight tyrosine kinase inhibitors as anti-cancer agents

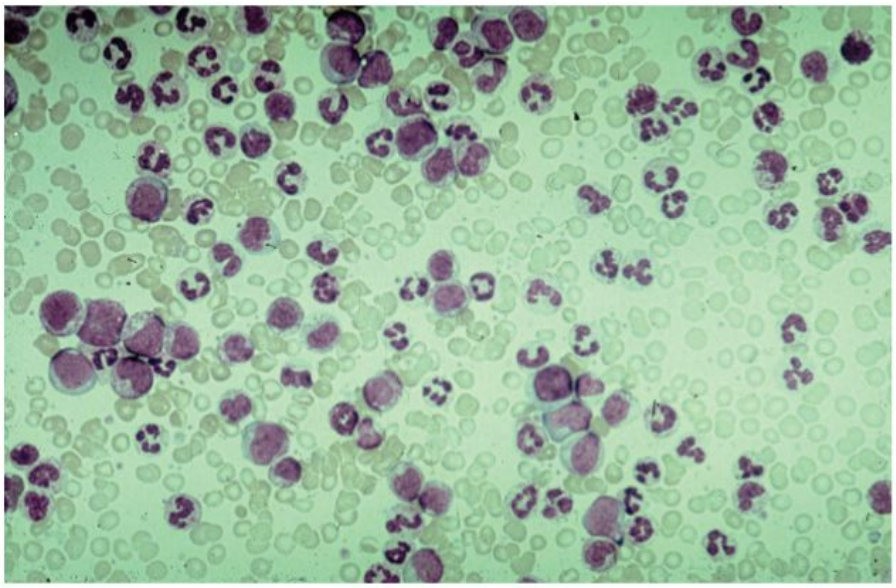
	Small molecule	**Antibody**
Target	tyrosine kinase domain	receptor ectodomain
Specificity	+++	++++
Binding	most are rapidly reversible	receptor internalized, only slowly regenerated
Dosing	oral daily	intravenous, ≤ weekly
Distribution in tissues	more complete	less complete
Toxicity	rash, diarrhea, pulmonary	rash, allergy
Antibody-dependent cellular cytotoxicity	no	possibly

Courtesy of N.J. Meropol and from N. Damjanov and N. Meropol, *Oncol. (Huntington)* 18:479–488, 2004.

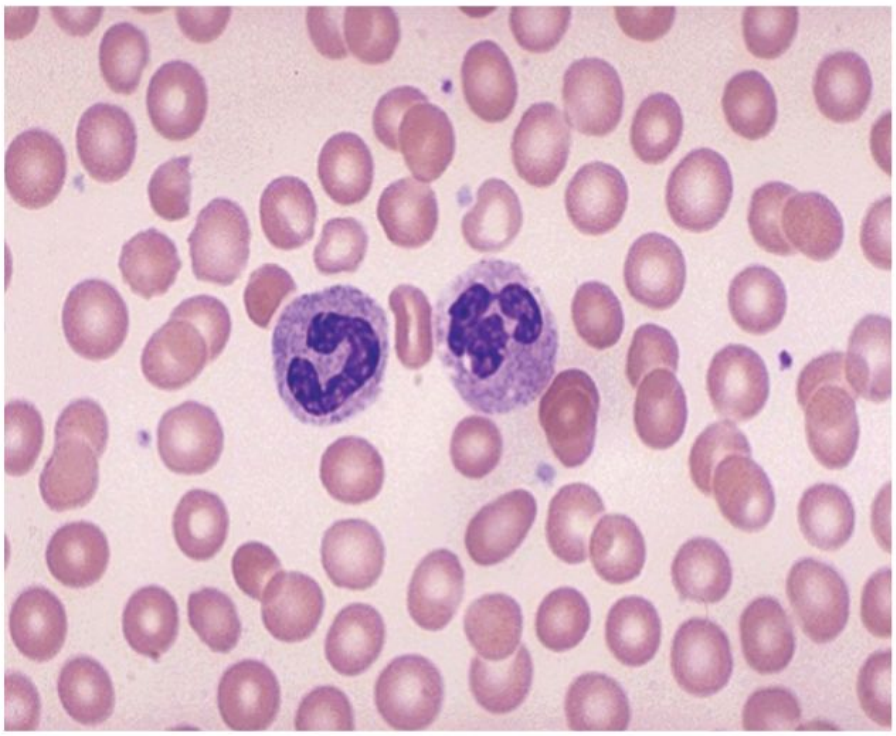
By 1996, Gleevec had been found able to inhibit the growth of CML cells *in vitro* while having no effect on normal bone marrow cells. More specifically, the proliferation of Bcr-Abl–dependent cells could be inhibited at drug concentrations as

low as 40 nM, indicating a high affinity of Gleevec for the catalytic cleft of the tyrosine kinase domain. (Cells that depend on Bcr-Abl for survival can be forced into apoptosis by Gleevec's inhibition of Abl kinase function.) The initial clinical trials, begun in 1998, revealed remissions from disease in all 31 treated CML patients, with only minimal side effects, even when taken daily for many years. Four years later, 6000 patients were participating in Gleevec clinical trials.

Treatment of early-stage (chronic) CML with Gleevec leads to a hematologic response in 90% of cases: microscopic analysis of blood smears reveals a profound shift in the cellular composition of the blood (**Figure 17.30A**), and PCR analysis reveals an extraordinary decline in the levels of the *Bcr-Abl* mRNA detectable in blood cells (Figure 17.30B). In 50% of these cases, the translocated Philadelphia chromosome is no longer detectable by karyotypic analyses of patients' white cells. About 60% of the patients who have already progressed to blast crisis respond to Gleevec, but they generally relapse after some months. In contrast, a clinical study reported in 2006 that five years after chronic-phase patients began long-term treatment with Gleevec, fewer than 5% of patients had died of CML-related effects. By this fifth year, the annual relapse rate (that is, progression to blast crisis) in this population was ~0.6%.



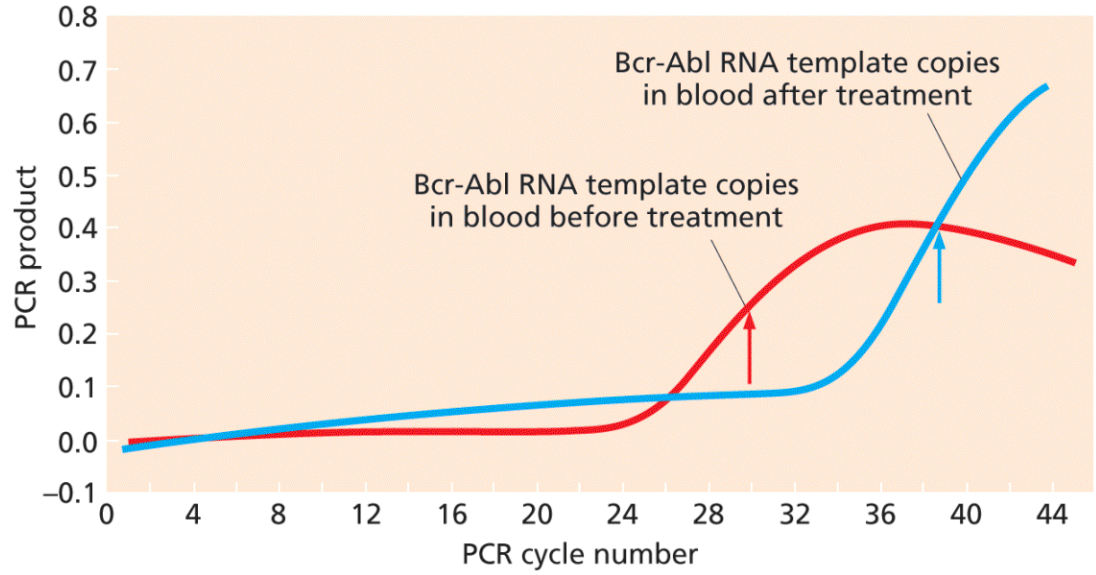
before treatment



after treatment

Two histology images of blood before and after treatment. The blood before has many cells with large dark nuclei among the red blood cells. The blood after has two purple cells among the red blood cells.

(A)



A graph shows the amount of P C R product relative to an increasing number of P C R cycles. On the x axis, the P C R cycle number ranges from 0 to 44. On the y axis, the amount of P C R product ranges from negative 0.1 to 0.8. There are two curves that both start near 0. The curve for B c r A b l R N A template copies in blood before treatment starts increasing around cycle 24 and peaks near 0.5 at cycle 36. The curve for B c r A b l R N A template copies in blood after treatment increases slowly to 0.1 at cycle 33 and then increases more rapidly to 0.7 at cycle 44.

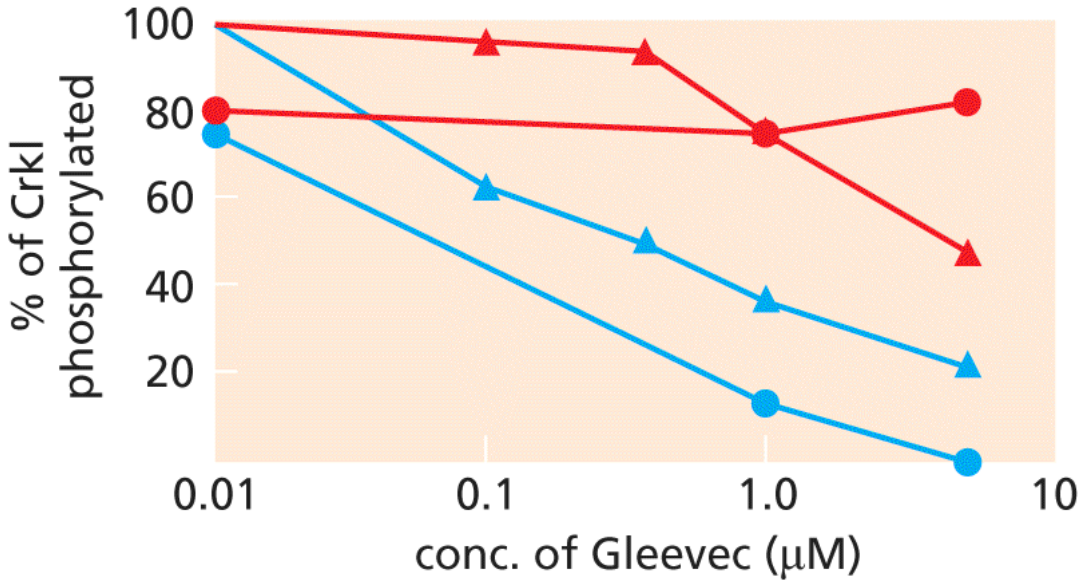
(B)

Figure 17.30 Measuring clinical responses to Gleevec treatment (A) The successes of Gleevec in treating chronic myelogenous leukemia (CML) can be gauged from cytological analyses of the patients' blood. As seen here, treatment with Gleevec converted the blood from a state with many leukemia cells (large, dark nuclei, *above*) to one in which only normal granulocytes are visible (*below*) among the red blood cells. (B) A more sensitive and quantitative measure of therapeutic success comes from use of quantitative polymerase chain reaction (qPCR) measurements of the level of Bcr-Abl mRNA (which is reverse-transcribed prior to PCR amplification). In an untreated patient (*red curve*), 50% of maximum (*red arrow*) PCR-mediated gene amplification is observed at about the 29th cycle of gene amplification (in which each cycle results in the doubling of the amplified sequence). Following Gleevec treatment (*blue curve*), a comparable degree of amplification is achieved only at about the 39th cycle (*blue arrow*), indicating that the Bcr-Abl mRNA–expressing cells are present at a level

that has been reduced by a factor of about 2^{10}. PCR-based assays can detect as few as one CML cell amid 10^5 to 10^6 normal blood cells. (A and B, courtesy of B.J. Druker.)

The molecular mechanisms that allow tumor cells to eventually escape Gleevec inhibition are interesting, in that they shed further light on the Bcr-Abl oncoprotein and its actions and, more generally, they reveal how cancer cells can acquire resistance to highly targeted drugs. Initial analyses of *Bcr-Abl* sequences in the tumors of patients with Gleevec-resistant, relapsed disease revealed that 29 of 32 tumors harbored mutations in the *Bcr-Abl* gene; altogether these yielded substitutions of 13 distinct amino acid residues in the kinase domain. Another dozen have been cataloged in subsequent studies.

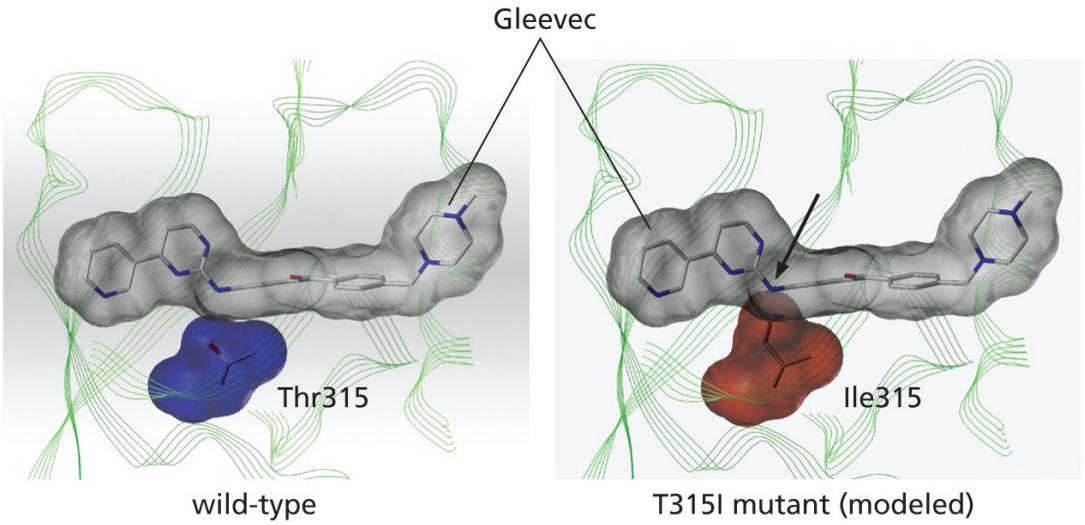
Some of these mutations prevent Gleevec from binding to the Abl catalytic cleft, either by directly interfering with its binding or, less directly, by promoting protein conformational changes that affect the dynamics of binding (**Figure 17.31A and B**). In a minority of patients, Gleevec resistance was achieved through amplification of the *Bcr-Abl* gene in their leukemia cells, yielding increased levels of the encoded oncoprotein that apparently could no longer be inhibited by the concentrations of drug used to treat patients (see Figure 17.31C).



A graph shows the percent of C r k l phosphorylated relative to the concentration of Gleevec for two different patients before and after treatment with Gleevec. On the x axis is concentration of Gleevec from 0 to 10 micromolar. On the y axis is percent of C r k l phosphorylated from 0 to 100.

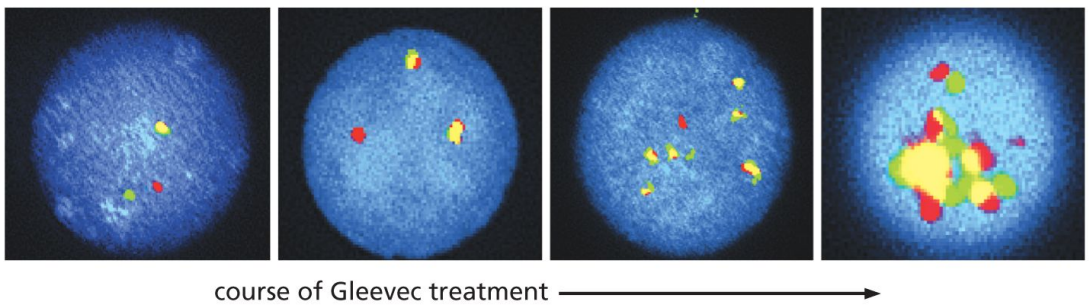
The blue triangle line starts near 100 percent and ends at 20 percent near a concentration of 8 micromolar. The blue circle line starts near 78 percent and ends at 0 percent near a concentration of 8 micromolar. The red triangle line starts at 100 percent and ends at 50 percent near a concentration of 8 micromolar. The red circle line starts at 80 percent and ends at 85 percent near a concentration of 8 micromolar.

(A)



Two illustrations show Gleevec in a wild type and a T 315 l mutant cell. In the wild type cell, Gleevec is bonded such that it just touches T h r 315. In the mutant cell, if Gleevec were to try to bind, it would overlap with I L e315.

(B)



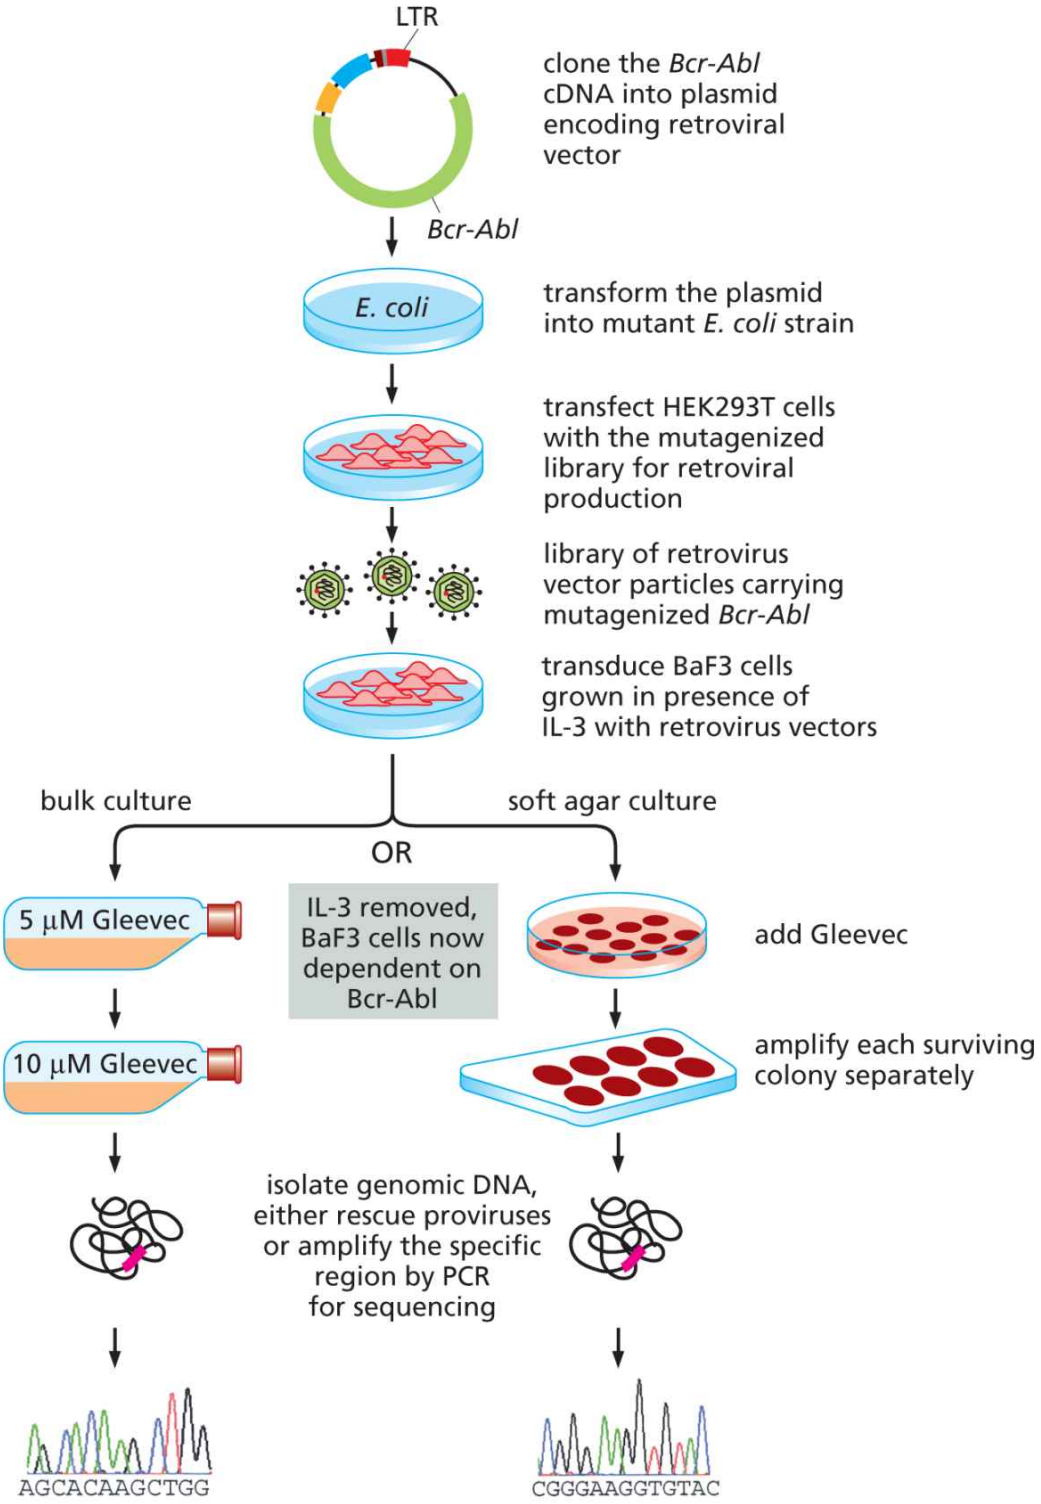
A series of fluorescence images shows changes over the course of Gleevec treatment. The first image has one small red dot, one small green dot, and one small yellow dot on a blue background. The second image has two slightly larger yellow dots and a red dot, with one small spot of green indicating overlap. The third image has several yellow dots and one red dot, with a few

green dots indicating overlap. The fourth image has several larger yellow masses and red splotches, with several green splotches indicating overlap. (C)

Figure 17.31 Acquisition by CML cells of resistance to Gleevec The ability of Gleevec to inhibit Bcr-Abl kinase activity changes dramatically following relapse and acquired resistance to drug treatment. (A) In this experiment, Bcr-Abl kinase activity was gauged in isolated leukemia cells by the degree of phosphorylation of Crkl, a protein that is a substrate for phosphorylation by this kinase. At the onset of therapy, the Bcr-Abl kinase (in cultured leukemia cells) suffered about a 50% inhibition in the presence of approximately 0.1 μM Gleevec in two patients (*blue triangles, blue circles*). However, after Gleevec resistance developed in these patients, about an 8-μM concentration of the drug was required to inhibit one patient's Bcr-Abl kinase (*red triangles*), while the other patient was totally resistant to the drug (*red circles*). (B) The Gleevec molecule is able to nestle tightly in a molecular cavity created in part by a threonine residue (*dark blue*) in residue position 315 of the wild-type Bcr-Abl oncoprotein (*left*; see also Figure 16.10C). However, in a mutant Bcr-Abl found in the leukemic cells of a Gleevec-resistant patient (*right*), this threonine residue was replaced by an isoleucine (*brown, arrow*), which protrudes into the drug-binding cavity and interferes with insertion of Gleevec into the cavity. (C) The number of *Bcr-Abl* gene copies in a patient's leukemic cells has been gauged here using fluorescence *in situ* hybridization (FISH). Nuclei are visualized here in *blue*, ABL sequences in *red*, and BCR sequences in *green*. Yellow indicates an overlap of ABL and BCR sequences, i.e., sites of the fused gene created by the chromosomal translocation. The copy numbers of the fused gene (*yellow*) at the beginning of therapy (*left*) were quite low, but as treatment proceeded (*rightward*), the copies of the fused gene (and therefore Bcr-Abl fusion protein) increased progressively until the patient's leukemia became resistant to Gleevec treatment. In this particular patient, Gleevec resistance was acquired by the tumor cells because the fusion protein became overexpressed, thereby exceeding the ability of the normally used therapeutic concentration of Gleevec to bind and fully inactivate it. (From M.E. Gorre et al., *Science* 293:876–880, 2001. With permission from AAAS.)

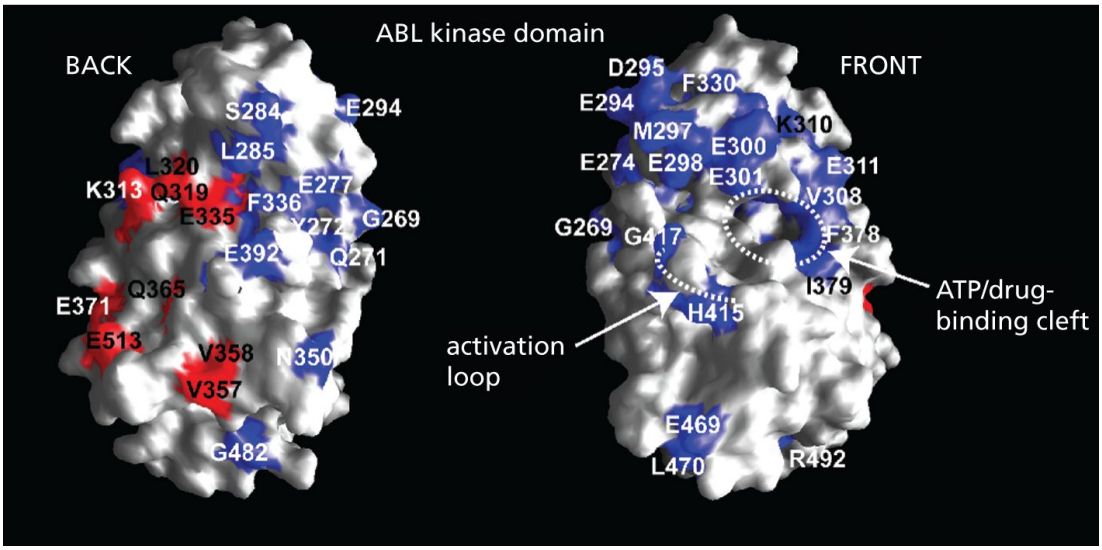
The observations that acquired resistance to Gleevec is usually accompanied by either structural alterations or overexpression of the Bcr-Abl protein provide compelling proof that Gleevec's therapeutic responses can be attributed directly to its effects on the Bcr-Abl protein. This insight was further explored by introducing random mutations into a vector encoding the Bcr-Abl protein and then determining which of the resulting mutant forms of this protein were able to resist inhibition by Gleevec (**Figure 17.32**). Such an experimental strategy, which uses cultured cells whose growth and viability are dependent on Bcr-Abl (see Figure 17.21), can in principle

reveal the full spectrum of structural alterations of Bcr-Abl that are capable of rendering it resistant to Gleevec inhibition and thereby advance our understanding of the molecular mechanisms underlying acquired drug resistance.



A flow chart shows the process of screening for drug resistant variants of B c r A b l. The first step is to clone the B c r A b l c D N A into a plasmid encoding retroviral vector. The plasmid is then transformed into a mutant E coli strain in a petri dish. The next step is to transfect H E K 293 T cells with the mutagenized library for production. This produces a library of retrovirus vector particles carrying mutagenized B c r A b l. The next step is to transduce B a F 3 cells grown in the presence of I L 3 with the retrovirus vectors. This may be put in a bulk culture with 5 micromolar Gleevec and then with 10 micromolar Gleevec. If it is instead put in a soft agar culture, Gleevec is added and then each surviving colony is amplified separately. In both situations, I L 3 is removed so that the B a F 3 cells are now dependent on B c r A b l. After each of these processes, genomic D N A is isolated. The next step is either to rescue the proviruses of amplify the specific region by P C R for sequencing.

(A)



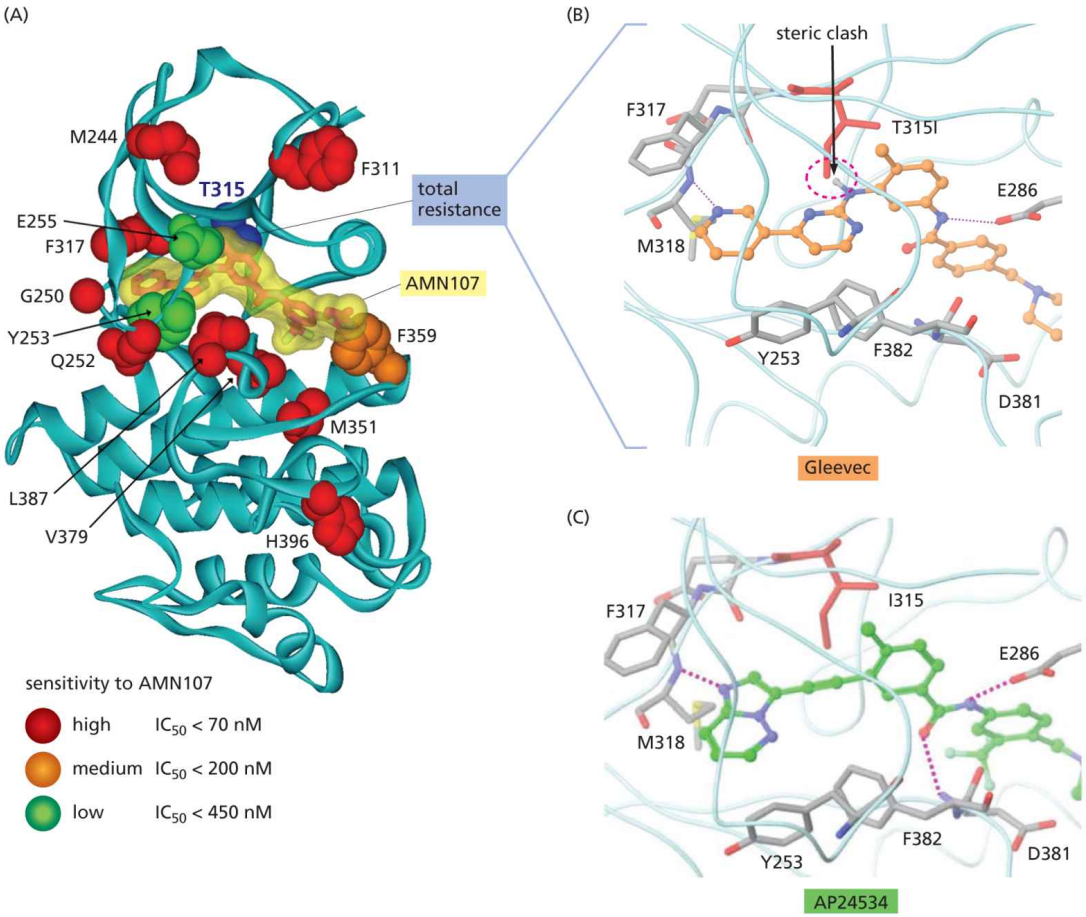
A 3 D model of the A B L kinase domain of a Gleevec resistant B c r A b l protein. Both sides of the lumpy, ovular mass are shown with different regions highlighted and labeled. Two regions close together are identified as the activation loop and the A T P slash drug binding cleft.

(B)

Figure 17.32 Screening *in vitro* for Gleevec-resistant mutant forms of Bcr-Abl
One strategy for detecting drug-resistant variants of Bcr-Abl involves cultured cells such as BaF3 cells (see Figure 16.15), whose continued survival can be made dependent on the presence of a functionally active Bcr-Abl oncoprotein. When

such Bcr-Abl–expressing cells are treated with Gleevec, they are killed because of their dependence on continued Bcr-Abl signaling. (A) A cDNA clone expressing the “wild-type” Bcr-Abl protein (i.e., the direct product of the chromosomal translocation) can be mutagenized by passage through *E. coli* bacteria that are highly error-prone in DNA replication and therefore generate mutant variants of the introduced, plasmid-borne *Bcr-Abl* sequence. The resulting collection of randomly mutated Bcr-Abl–expressing clones is then introduced, via a retrovirus vector, into BaF3 cells, which are then exposed to Gleevec. The rare cells that resist being killed by Gleevec are isolated, and the sequence of the mutant Bcr-Abl protein that conferred Gleevec resistance is determined. (B) When these Gleevec-resistant mutant Bcr-Abl proteins are analyzed, many are found to have single amino acid substitutions of residues located throughout the Abl kinase domain. The “back” and “front” of the Abl kinase domain are shown here, together with the sites of these mutant residues and the identities of the normally present amino acid residues. Surprisingly, the individual mutations, each of which confers Gleevec resistance, alter residues at many sites in the ABL domain, indicating that CML cells have multiple options for developing drug resistance. Many of these mutant residues are found on the back side of Abl opposite the catalytic cleft; some of these residues (*red*) participate in interactions between the kinase (i.e., SH1) domain and the SH2 and SH3 domains of Abl (*not shown*). Other mutant sites (*blue*) produce drug resistance through poorly understood mechanisms. This *in vitro* screen for Gleevec-resistant Bcr-Abl mutants revealed most of those discovered in patients plus a number of previously undocumented ones. (From M. Azam, R.R. Latek and G.Q. Daley, *Cell* 112:831–843, 2003. With permission from Elsevier.)

A number of second-generation Bcr-Abl inhibitors have been synthesized that succeed in inhibiting many of the mutant Gleevec-resistant Bcr-Abl proteins that arise in CML patients and trigger clinical relapse; among these are nilotinib and dasatinib, which are actually more potent than Gleevec/imatinib. However, they and other newly developed Abl inhibitors fail to shut down the most formidable of the mutant proteins, termed T315I (**Figure 17.33A and B**). Detailed structural analyses of this mutant protein and its effects on drug binding have, after much effort, yielded novel compounds, including ponatinib, that can also shut down this particular mutant kinase (Figure 17.33C), illustrating once again how a convergence of structural biology and synthetic organic chemistry can often cope with such refractory mutant enzymes.



Three models show different inhibitors of B c r A b l. Part A. A ribbon model of B c R A b l with A M N 107 bound in the tyrosine kinase domain. Points of high sensitivity surround the molecule and lead to total resistance. There are a few points of medium and low sensitivity. Part B. A model shows Gleevec binding in the tyrosine kinase domain of a mutant B c r A b l. The molecule has a steric clash with the protein and the structures overlap. Part C. A model shows A P 24 534 binding in the tyrosine kinase domain of a mutant B c r A b l. The molecule hydrogen bonds with different locations and does not have a steric clash.

Figure 17.33 Backup inhibitors of Bcr-Abl for patients with Gleevec-resistant tumors The fact that patients in the acute (blast crisis) phase of CML often develop resistance to Gleevec (see, for example, Figure 17.31) has stimulated the development of alternative inhibitors of the Abl tyrosine kinase. (A) One of these inhibitors, AMN107, which is ~20 times more potent than Gleevec against unmutated Bcr-Abl, is shown here (*orange stick figure in yellow envelope*) in complex with the tyrosine kinase domain of Bcr-Abl, on which are also indicated the sites of a number of amino acid substitutions found in the mutant forms of Bcr-Abl in tumors of Gleevec-resistant patients. (The number of colored spheres at a site indicates the number of atoms present in the side chain of the substituted

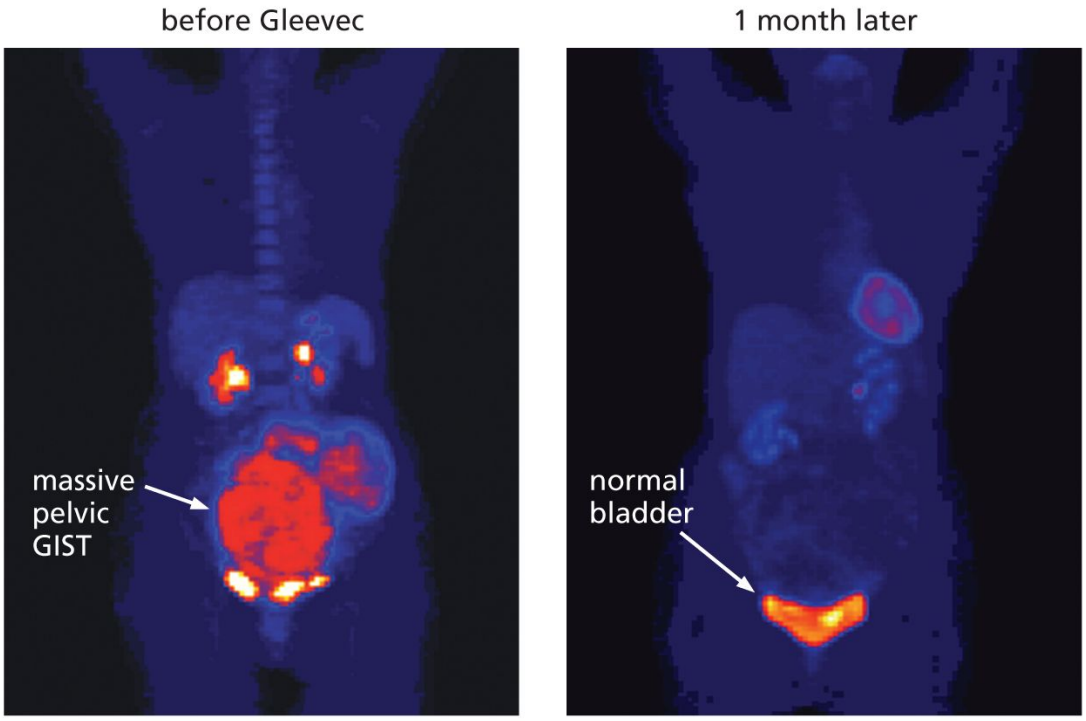
amino acid.) The locations of the amino acid substitutions carried by the mutant, Gleevec-resistant Bcr-Abl proteins are indicated by the red, orange, and green spheres and show different levels of sensitivity to inhibition by AMN107 (*below*). One Gleevec-resistant mutant form of Bcr-Abl in which the normally present threonine is replaced by an isoleucine (T315I; *blue spheres*) is also totally resistant to AMN107 and most other second-generation Bcr-Abl inhibitors. (IC_{50}, concentration required for 50% inhibition of the target molecule.) (B) As seen here, the side chain of the isoleucine (*red*) present in the T315I mutant Bcr-Abl protein creates a steric clash with a hydrogen atom of Gleevec in the drug-binding pocket (see Figure 17.31B), effectively precluding binding by Gleevec (*left*). (C) In response to this resistance of the T315I mutant, a pharmacologically active derivative of Gleevec, termed AP24534, avoids the steric clash and therefore can bind the T315I mutant protein. (A, from T. O'Hare et al., *Cancer Res*. 65:4500–4505, 2005. With permission from American Association for Cancer Research. B and C, from T. O'Hare et al., *Cancer Cell* 16:401–412, 2009. With permission from Elsevier.)

The ability of Gleevec to also inhibit the platelet-derived growth factor receptors (PDGF-Rα and β) suggested that it might prove useful in treating other types of malignancies as well. For example, translocations of the genes encoding these two receptors that cause constitutive receptor activation have been found in a number of chronic myeloproliferative diseases, that is, conditions involving elevated levels in the circulation of one or another cell type arising from the myeloid lineage of hematopoiesis. Indeed, patients suffering from hypereosinophilic syndrome that have PDGF-R translocations have shown a complete response following Gleevec treatment, with virtual disappearance of their eosinophils.

The growth of many of the far more common glioblastomas is driven by PDGF–PDGF-R autocrine loops (see Figure 5.8C). In this instance, however, the use of Gleevec administered together with cytotoxic drugs has not proven encouraging, possibly because it cannot efficiently penetrate the blood–brain barrier and gain access to the tumor parenchyma.

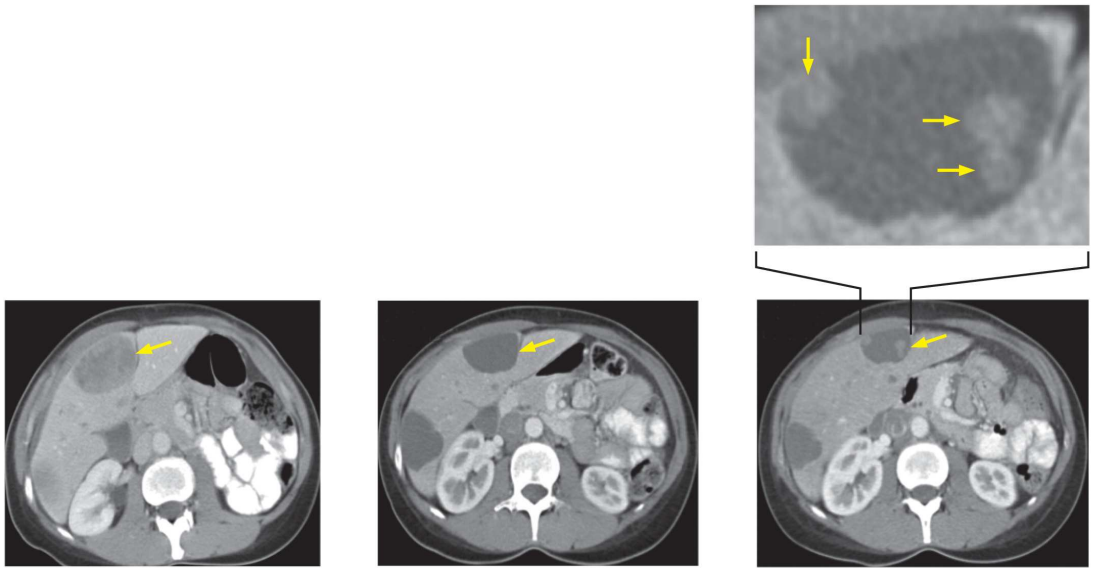
Gleevec's effects on a third tyrosine kinase—the Kit receptor—also make it an attractive agent for attacking gastrointestinal stromal tumors (GISTs), a relatively uncommon sarcomatous tumor for which few therapeutic options have been available. The Kit receptor is mutated in the majority (~85%) of these cancers, while a minority (3–5%) exhibit mutant PDGF-Rα—both targets of Gleevec. The mutant receptors fire constitutively in these tumors and seem to represent the primary mitogenic drivers operating in the tumor cells (see Figure 5.17). In one study, clear regression of the tumor was observed in almost 70% of treated patients (**Figure 17.34A**). By 2005,

SU11248—a second inhibitor of Kit tyrosine kinase function—was approved by the FDA for the treatment of GISTs, including those that had developed a resistance to Gleevec. When used as an adjuvant following surgical excision of localized primary tumors, Gleevec treatment offers long-term survival that may result in a cure. With metastatic disease, however, Gleevec can cause regression of GIST lesions, but within a year or two, tumors reappear (see Figure 17.34B).



Two images show a scan of a patient’s abdomen before and after Gleevec treatment. The patient’s body is mostly a dark blue color. Before Gleevec, there is a bright red massive pelvic G I S T that takes up most of space in the lower abdomen. One month later, a much smaller portion is red, which is characteristic of a normal bladder.

(A)



A series of C T scans of a patient's abdomen. In the initial presentation, a large light gray oval is present in the liver. After 1 month on Gleevec, there are now two dark gray spots. After 9 months on Gleevec, the dark gray spots are smaller but within one of them are three lighter gray spots.

(B)

Figure 17.34 Use of Gleevec to treat gastrointestinal stromal tumors Gleevec also shows inhibitory activity against the tyrosine kinase function of the Kit receptor, which suggested that it might prove useful against gastrointestinal stromal tumors (GISTs), in which mutant, constitutively active Kit receptors are commonly found. (A) As seen here, this patient's GIST (red mass, pelvic region, *left image*), which was visualized because of its uptake of a labeled glucose analog, responded dramatically to Gleevec treatment (*right image*). (The residual labeling following treatment reflects the accumulation of the labeled dye in the patient's bladder.) (B) Despite initial anti-tumor activity in nearly 90% of patients, resistance to Gleevec develops in most GIST patients; after two years, about 50% of tumors worsen despite continuing Gleevec treatment. Seen here are computed tomography (CT) scans of a patient with advanced GIST demonstrating several metastatic lesions growing in the liver (one with *yellow arrow*, *left panel*). After one month of daily Gleevec (= imatinib) treatment, the metastases, previously a lightly mottled *gray*, become more solidly dark, indicating the increased water density following widespread tumor cell apoptosis and degeneration (*middle panel*). However, after nine months of Gleevec (*right panel*), three light spots have appeared within the dark mass that was the original tumor (*yellow arrow*), indicating the eruption of robustly growing subpopulations that signal the onset of clinical resistance to targeted therapy (*yellow arrows, top right*). In this particular

patient, each of the three recurring growths carried its own novel secondary point mutation in the *Kit* gene in addition to the initiating *Kit* mutation that launched the tumor in the first place, leading in each case to a doubly mutated *KIT* allele. (Courtesy of G.D. Demetri.)

The clear successes of Gleevec represented the first validation that rational drug design can succeed in producing agents that are highly useful for treating various types of human cancer. It was initially viewed as a disadvantage that Gleevec interferes with multiple tyrosine kinases, because it was feared that this broader activity would lead to unacceptable side effects. However, with the passage of time, it is increasingly clear that such multi-target effects may actually prove useful in treating certain malignancies. Indeed, second and third generation Bcr-Abl inhibitors engage an even broader range of kinase targets. Dasatinib, for example, targets Abl, Src kinase, and c-Kit at dose ranges of less than 1 nanomolar. Here, as in many examples of kinase inhibitors, higher affinity interaction for a given target is accompanied by increased affinity to many targets (and, consequently, decreased overall drug specificity). This broader activity plays a critical role in the treatment of another Bcr-Abl-driven malignancy, a Philadephia chromosome-positive subset of B-cell leukemia, termed Ph+ B-ALL. Unlike CML, Gleevec-treated Ph+ B-cell acute lymphocytic leukemias frequently relapse during treatment and, in roughly one-third of these cancers, relapses occur in the absence of Bcr-Abl mutations. Dasatinib and ponatinib have proven more effective in treating these leukemias, presumably because they are able to inhibit both Bcr-Abl and other pro-survival kinase-driven pathways operating in these cells.

The successes of ponatinib in targeting CMLs bearing T315I mutations and Ph+ B-ALLs led to attempted use of this agent as first-line therapy for these cancers. However, clinical trials of this agent were halted after bleeding issues from thrombocytopenia and stenosis in small and large blood vessels appeared. Use of this agent was subsequently limited to the treatment of treatment-resistant CML and Ph+ B-ALL. Thus, the viability and proliferation of the neoplastic cells in many tumors depend on the coordinated actions of multiple tyrosine kinases, and the ability to strike at several of these simultaneously may one day be found to confer great therapeutic advantage. However, broadly acting kinase inhibitors can also yield unexpected toxicity that limits or prevents their use in the oncology clinic.

Unfortunately, in CML, the continued presence of cancer stem cells (CSCs) limits the ability of Gleevec to definitively cure patients (Sidebar 17.13). Recall that research on human cancers, including hematopoietic tumors, breast carcinomas, and brain tumors, has revealed that CSCs often constitute only a small proportion (<<5%) of the neoplastic cells in these tumors and that their existence can be revealed only by the biological test of their tumor-forming ability or by the use of fluorescence-activated cell sorting (FACS; see Section 11.7). As it happens, Gleevec is quite potent in killing

actively cycling leukemia cells (that is, the “transit-amplifying” or “progenitor” cells; see Section 11.7). However, most of the cells in the neoplastic stem cell population, which are outside the active cell cycle at any single point in time (see Section 8.1), are not dependent on Bcr-Abl-mediated signaling for their continued survival and have proven to be quite resistant to drug treatment.

The CSCs are usually present in minute numbers in a CML patient undergoing Gleevec therapy, being detectable only by highly sensitive PCR-based assays. However, if treatment is halted, the CSCs usually re-enter into the growth-and-division cycle and regenerate transit-amplifying progeny, soon leading to regrowth of the malignancy and clinical relapse (**Figure 17.35A**). This seems to explain why Gleevec treatment needs to be chronic and why, in the future, drug development needs to be focused on agents that strike at the cores of tumors by destroying their stem cells (**Sidebar 17.13**).

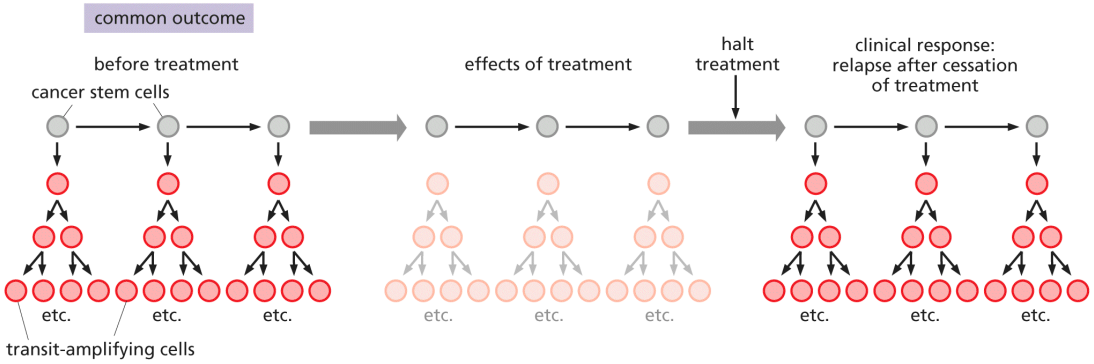
Sidebar 17.13 Cancer stem cells greatly complicate the evaluation of anti-cancer therapies

The existence of cancer stem cells (CSCs) in many solid tumors has profound implications for the evaluation of many types of anti-cancer treatments. These lessons are illustrated graphically in the case of CML and Gleevec. [In the hypothetical case shown in Figure 17.35A, the re-emergence of a tumor is triggered by cessation of treatment, but for most tumors under treatment, such relapses occur because tumor cells have developed resistance to the therapeutic agents.] In carcinomas, for example, the CSCs, which display certain mesenchymal characteristics, seem generally to be more resistant to existing therapeutic regimens than most of the neoplastic cells in these tumors (see Table 17.5). Hence, a therapy may eliminate the bulk of a tumor (leading to a significant clinical response), while leaving behind a residue of clinically undetectable CSCs; the latter may then re-launch tumor growth when the therapy is halted or when drug resistance develops. Clinically, this behavior is sometimes called the “dandelion effect,” referring to the rapid re-emergence of weeds in a lawn following mowing, which cuts off their leaves but leaves their roots intact.

This logic suggests that the ability to eliminate CSCs will be the key to generating durable clinical responses for many types of tumors (Figure 17.35B). However, such elimination on its own may not suffice, because there are indications from studies of tumor xenografts that the transit-amplifying/progenitor cells can dedifferentiate and thereby regenerate new CSCs under certain physiological conditions (Figure 17.35C). Together, this would indicate that both the CSCs and the non-CSCs within a tumor need to be eliminated in order to prevent recurrence and clinical relapse. Importantly, identifying agents that specifically eliminate CSCs may be challenging, because such

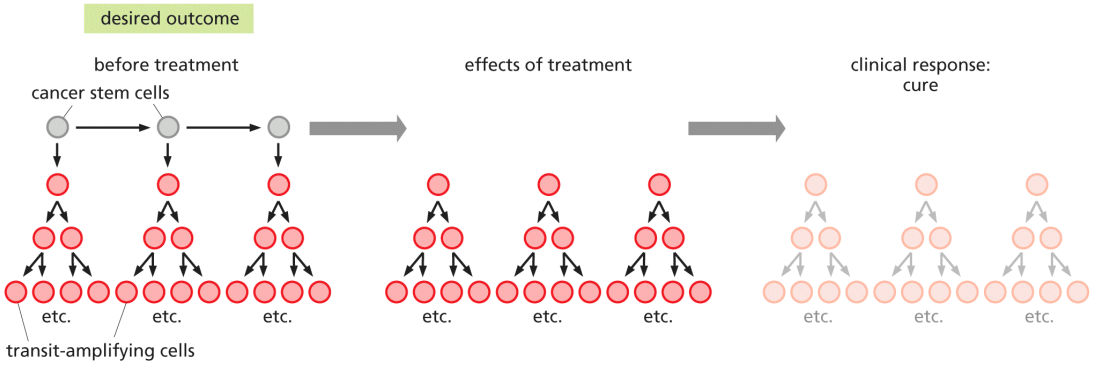
drugs may, on their own, have minimal effects on the overall sizes of tumor masses and may therefore be judged to be unworthy of further development.

In fact, rituximab, the anti-CD20 monoclonal antibody that is used to treat B-cell tumors (see Section 15.19), shows just this behavior: it eliminates the CSCs of multiple myelomas but not the more differentiated, far more abundant antibody-secreting cells that form the bulk of these tumors. (Fortunately, early in its development, rituximab was recognized to have efficacy for treating a wide range of B-lymphocyte–lineage tumors and was therefore approved for further development and introduction into the clinic.)



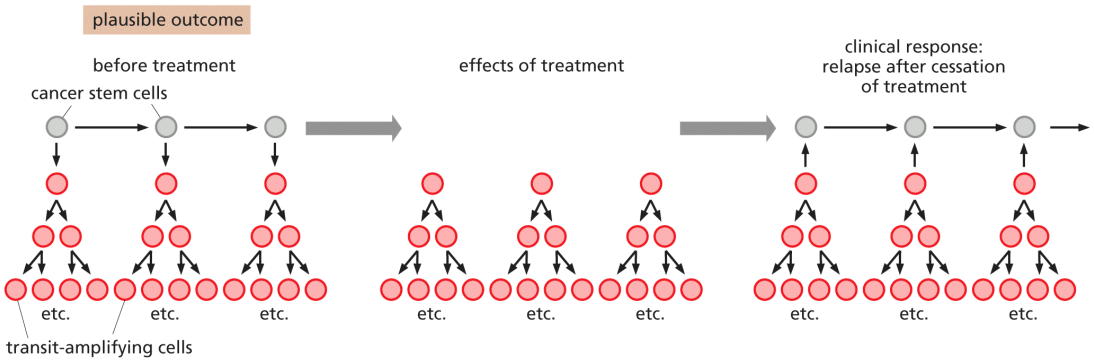
A set of genealogy trees shows the common outcome. Before treatment, each cancer stem cell produces a cancer cell that reproduces such that the number of cancer cells doubles with each generation. These are called transit-amplifying cells. During treatment, the transit-amplifying cells do not form but the stem cells remain. After treatment is stopped, the clinical response is a relapse and the transit-amplifying cells return after cessation of treatment.

(A)



A set of genealogy trees shows the desired outcome. Before treatment, each cancer stem cell produces a cancer cell that reproduces such that the number

of cancer cells doubles with each generation. These are called transit-amplifying cells. During treatment, the stem cells are removed but the transit amplifying cells remain. After treatment is stopped, the clinical response is a cure and the transit amplifying cells disappear as well.
(B)



A set of genealogy trees shows the plausible outcome. Before treatment, each cancer stem cell produces a cancer cell that reproduces such that the number of cancer cells doubles with each generation. These are called transit-amplifying cells. During treatment, the stem cells are removed but the transit amplifying cells remain. After treatment is stopped, the clinical response is a relapse and the transit amplifying cells produce new stem cells after cessation of treatment.

(C)

Figure 17.35 Role of tumor stem cells in the response to anti-cancer treatments Although the evidence is still fragmentary, it appears that in many and perhaps all tumors (see Section 11.6), a small proportion of the neoplastic cell population is composed of self-renewing cancer stem cells (*gray*). These spawn the bulk of the cancer cells in tumors (*pink*), which have many of the properties of normal progenitor/transit-amplifying cells, as well as more differentiated progeny. (A) If, as occurs with Gleevec, an anti-cancer therapy results in the depletion of the neoplastic transit-amplifying cells without eliminating the cancer stem cells (CSCs), then the latter can regenerate the tumor soon after that therapy is halted (*right*). Indeed, diverse sources of evidence indicate that in many carcinomas the CSCs are significantly more resistant to therapy than the majority of carcinoma cells. Hence, CSCs are doubly dangerous in that they can survive treatment and are capable of generating entirely new tumors in both primary tumor sites and in distant tissues. (B) In response to the risk posed by CSCs, some researchers have undertaken to discover agents that preferentially eliminate these cells, with the thought that their elimination will lead to the disappearance of entire tumors, because their source of self-renewal has been eliminated (*right*). (C) Elimination

of CSCs, by itself, may not lead to a cure because newer evidence has indicated (*right*) that the non-CSCs in certain tumors can spontaneously generate new CSCs. Hence, the targeting of both populations (CSCs and non-CSCs) may be required to develop durable clinical responses following treatment of a variety of tumors.

As mentioned, Gleevec also fails to effectively treat CML that has progressed to an advanced blast crisis phase. In this phase, tumor cells no longer exhibit a myeloid-like appearance and resemble, instead, undifferentiated progenitor cells. Indeed, these cells cytologically resemble tumor cells present in treatment-refractory Ph+ B-ALL. These cells express Bcr-Abl but fail to incur durable responses to Bcr-Abl inhibitors. This explains why patients need to be treated with Gleevec prior to leukemia progression to blast crisis, at which point Gleevec and similarly acting drugs lose much of their efficacy.

Nonetheless, if a drug such as Gleevec succeeds in generating clinical remissions that are durable over many years' time, its inability to kill the stem cells of a CML and the requirement to administer drug early in disease progression is clearly an acceptable shortcoming. In any case, Gleevec represents a major triumph of anti-cancer drug development, because it is vastly superior to all alternative treatments of this otherwise-inexorably progressing disease.

Of note, the striking success of Gleevec in treating CML persuaded many that comparable successes would soon emerge for treating a number of other malignancies driven by deregulated tyrosine kinases. As it turned out, CML is a rather unique entity among adult tumors, in that almost all these leukemias share a common genetic driver (the Bcr-Abl translocation) to which they are all addicted, while carrying few if any additional chromosomal aberrations and oncogenic mutations. In addition, rather than being full-fledged malignant cells, the leukemic cells present in the chronic phase of CML have been likened to *in situ* carcinomas in the breast and early adenomas in the gut (see Section 11.2). These attributes set the chronic-phase cells apart from most adult tumors and help to explain the striking differences between the clinical responses of CML to Gleevec versus the mixed responses of many carcinomas to the other tyrosine kinase inhibitors (TKIs) described below. (In retrospect, the stunning successes of Gleevec inspired unrealistically high expectations for the many TKIs that followed.)

OceanofPDF.com

Glossary

myeloproliferative
: Referring to excessive proliferation and resulting elevated levels of one of the several cell types generated by the myeloid branch of the hematopoietic system.

hypereosinophilic
: Referring to a syndrome with elevated levels of eosinophils in the circulation. *See* **eosinophil**.

complete response
: Elimination of all detectable neoplastic tissue following an anti-cancer therapy. *See also* **partial response**.

blood–brain barrier
: The barrier created by specialized endothelial cells and basement membrane that operates, together with astrocytes, to prevent transport of solutes between the blood and the parenchyma of the brain.

first-line therapy
: The mode of therapy that is initially employed to treat a patient, usually because it is considered most likely to elicit a desired clinical response; failure of this initial therapy often leads to the use of second-line treatments. *See also* **second-line therapy**.

blast crisis
: Clinical state occurring when a hematopoietic tumor that has been under therapeutic control relapses into a highly aggressive stage of disease progression in which the erupting tumor cells are in a primitive state of differentiation. *See* **blast**.

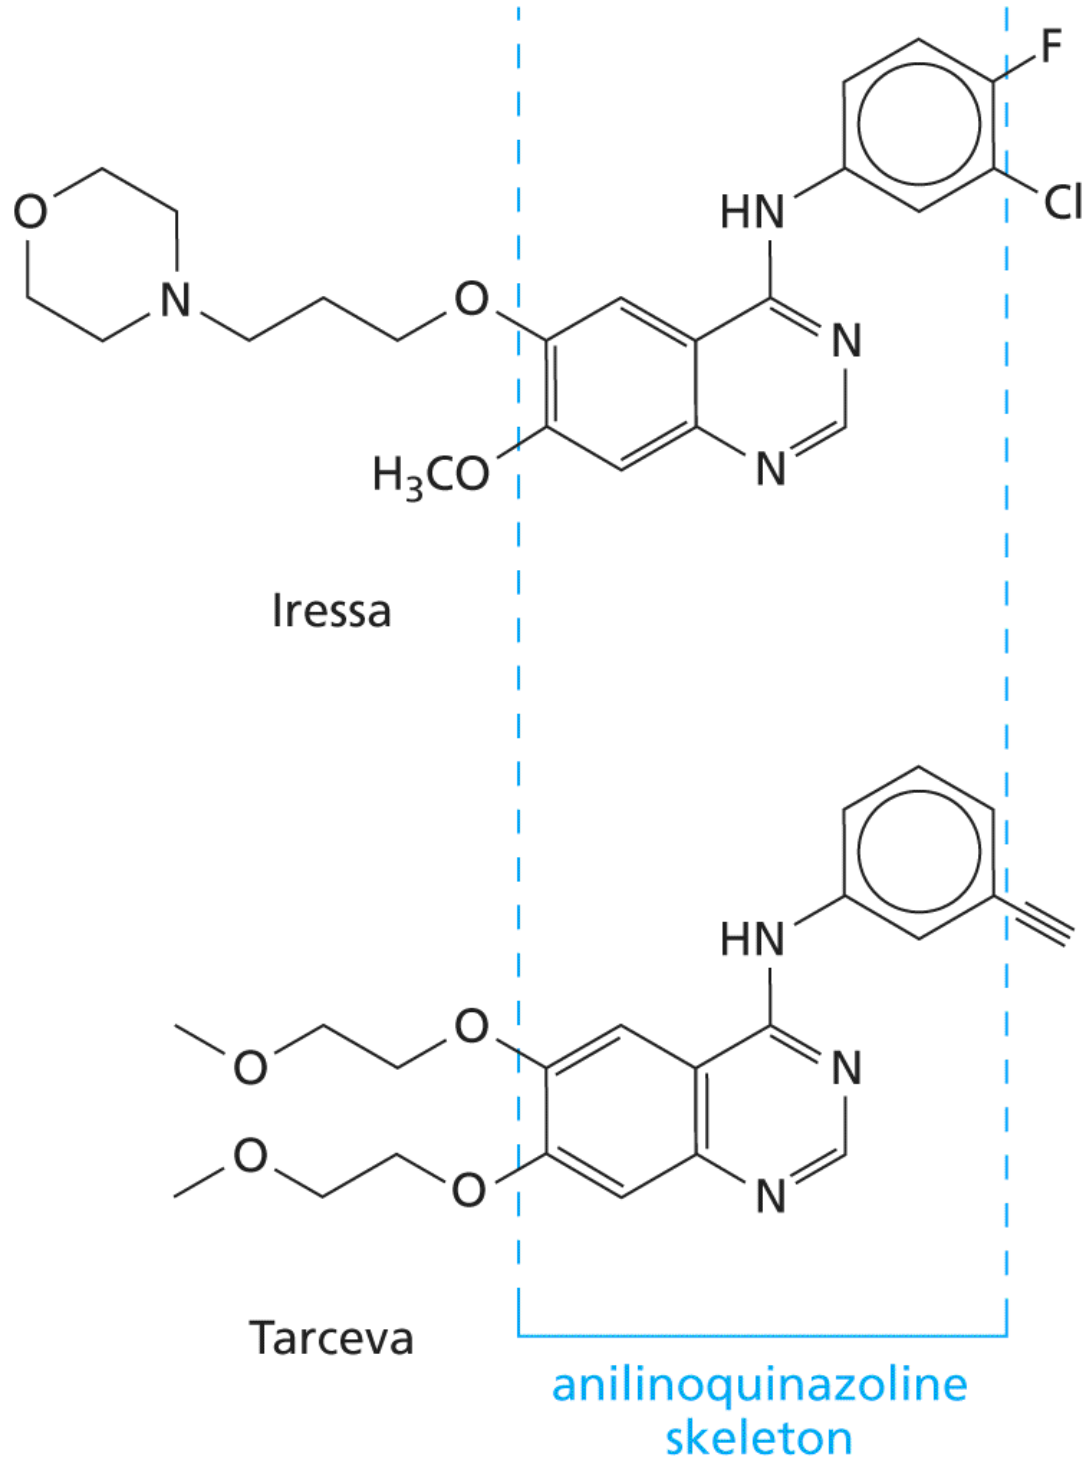
17.14 EGF receptor antagonists may be useful for treating a wide variety of tumor types

The proposal to develop Gleevec initially met with considerable resistance in the pharmaceutical company where it originated, simply because the market for this drug was judged to be too small to justify the high costs of its development and testing in the clinic. The same could not be said of the class of drugs designed to inhibit the epidermal growth factor receptor (EGF-R). Carcinomas are common tumors, and this receptor is believed to play a key role in the development of as many as one-third of them, being frequently overexpressed.

At least six distinct EGF-related ligands, including EGF itself, have been found to bind and activate the EGF-R. This means that even in those carcinomas in which the EGF-R is not overexpressed, it may nonetheless emit critical oncogenic signals through autocrine or paracrine signaling loops that are driven by the presence of one or more of its ligands in the interstitial space surrounding individual tumor cells. As one example of paracrine signaling, recall the release of EGF by macrophages that confers invasiveness on nearby breast cancer cells (see Figure 14.22).

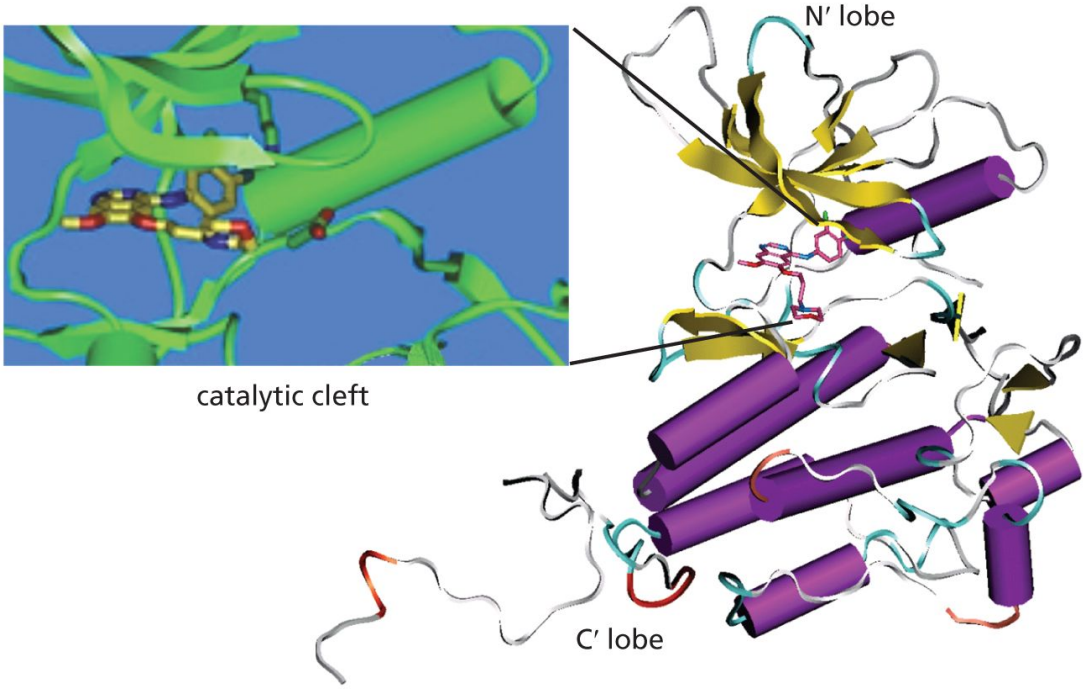
An alternative role of EGF-R in carcinoma pathogenesis is illustrated by breast carcinomas that overexpress the HER2/neu receptor. The oncogenic actions of this protein depend on its ability to form heterodimers with its cousin, the EGF-R; in such heterodimers, the EGF-R can phosphorylate the C′-terminal tail of HER2/neu, thereby activating signaling by the latter through the formation of multiple phosphotyrosines on its C-terminal tail (see Section 5.6).

The first clinically effective inhibitors developed to target the EGF-R tyrosine kinase were the drugs Iressa, also known as gefitinib/ZD1839, and Tarceva, also called either erlotinib or OSI-774 (**Figure 17.36A**). The two drugs have very similar but not identical properties and act by blocking the ATP-binding site of the receptor-associated kinase (Figure 17.36B; see also Figure 17.17). Once cancer cells are deprived of receptor signaling through inhibition of the EGF-R, they should lose the benefit of the strong mitogenic and anti-apoptotic signals that it generates. For example, in many types of epithelial cells, the continuous firing of the EGF-R sustains expression of Bcl-X_L (the potently anti-apoptotic cousin of Bcl-2) and, acting via MAPK, drives phosphorylation and attendant functional inactivation of the pro-apoptotic Bad protein (see Section 9.13, Figure 9.23B).



The molecular structures of Iressa and Tarceva. They both have an anilinoquinazoline skeleton with different side chains attached. the anilinoquinazoline skeleton consists of two six membered rings fused together. One is a benzene ring, onto which the side chains bind. The other has four carbon atoms and two nitrogen atoms. Bonded to the carbon atom that is

in between the benzene ring and a nitrogen atom, is a nitrogen atom that is further bonded to a benzene ring. In Iressa, this benzene ring is bonded to a fluorine and a chlorine. In Tarceva, it is bonded to a two carbon chain that has a triple bond.
(A)



A ribbon model of E G F R tyrosine kinase shows the binding site of Iressa and Tarceva. It has an N lobe of mainly beta sheets and a C lobe of mainly alpha helices. The drug binds in between these two lobes in the catalytic cleft.

(B)

Figure 17.36 Iressa and Tarceva (A) The two epidermal growth factor receptor (EGF-R) antagonists are constructed from a common anilinoquinazoline skeleton, which confers on them an affinity for the ATP-binding site of the receptor tyrosine kinase. The chemical side groups that are attached to this skeleton have biological effects, because the effectiveness of the two drugs differs in treating, for example, non-small-cell lung carcinomas (NSCLCs). (B) Iressa, also termed ZD1839, binds to a very similar region of the EGF-R tyrosine kinase as does Tarceva (see Figure 17.17). A blown-up view (*left*) of the drug-binding site of the EGF-R tyrosine kinase domain (*right*) is shown here, with the drug molecule shown as a colored stick figure. This binding is so strong that 50% inhibition of the tyrosine kinase (TK) enzyme activity is achieved at a concentration of about 0.030 μM. (B, courtesy of A.C. Kay, AstraZeneca.)

Because Iressa and Tarceva target a cell surface receptor, their therapeutic utility must be compared with that of the monoclonal antibodies that also affect this receptor (see **Supplementary Sidebar 16.1**). In principle, these low–molecular-weight compounds should be able to penetrate into all the interstices of a solid tumor, including those where the far larger antibody molecules may have trouble gaining access (see Table 17.7). Also, it is generally far easier and less expensive to produce low–molecular-weight compounds on an industrial scale than it is to generate large quantities of monoclonal antibodies.

There are yet other possible advantages of low–molecular-weight tyrosine kinase inhibitors. For example, as we have read, in many human carcinomas, truncated forms of the EGF-R are expressed that lack the ectodomain; these mutant EGF-Rs may signal in a ligand-independent, constitutive fashion and therefore can function as potent oncoproteins (see Figure 5.8A). Similarly, about half of high-grade (that is, advanced) gliomas, termed glioblastoma multiforme (GBM), exhibit overexpressed EGF-R, and of these, about 40% display a form of the receptor that lacks the ectodomains specified by exons 2 through 7 of the EGF-R coding sequence. Such decapitated receptors cannot be bound by the monoclonal antibodies (MoAbs) that have been developed to recognize antigenic epitopes present in the ectodomain of the normal receptor protein. However, these aberrations should not derail the low–molecular-weight tyrosine kinase inhibitors, which target the cytoplasmic, signal-emitting domain of the receptor. Weighing against these drugs are their pharmacokinetic properties: as an example, Tarceva has a half-life of ∼36 hours, whereas the half-life of cetuximab (an anti-EGF-R monoclonal antibody) is >5 days and of Herceptin ~28 days.

Iressa has approximately a 50-fold more potent activity against the EGF-R–associated tyrosine kinase than against a number of other tyrosine kinases (see **Supplementary Sidebar 17.9**), and its initial use in the oncology clinic was reasonably encouraging. In the first clinical trials, 10% of patients with non-small-cell lung carcinomas (NSCLCs) showed partial responses to the drug, including disease stabilization of tumor growth; these patients tended to be women, nonsmokers, and those with the broncholaveolar subtype of lung cancers. A parallel study in Japan found a far higher rate (27%) of partial responses to Iressa; this difference, which continues to be observed, appears to represent a difference in the genetic constitutions of the Japanese versus Caucasian populations. (More generally, NSCLC tumors have represented difficult diseases to treat, as fewer than 15% of patients survive for five years following initial diagnosis.)

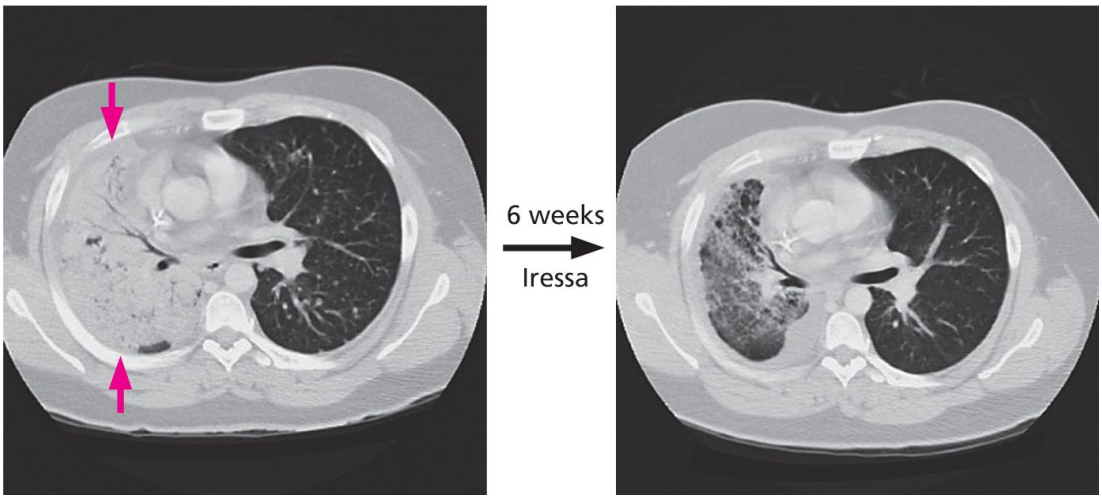
These outcomes were gratifying, if only because they represented clear responses in patients who otherwise had few if any other treatment alternatives. However, the hoped-for synergistic actions of Iressa with standard chemotherapeutic agents did not provide any survival advantage over standard chemotherapy used alone for the

treatment of NSCLC tumors, which together constitute almost 80% of lung cancer cases in the United States. When used on its own, Tarceva (but not Iressa) increased by two months the overall survival time of patients whose NSCLCs had become refractory to treatment by standard chemotherapeutic drugs.

Some valuable lessons were learned from these initial trials that may improve the responses in future clinical trials of these and similar drugs: First, the specific contribution of the EGF-R to the growth of the tumors under treatment was not documented. Hence, far greater response rates might have resulted from a stratification of the NSCLC patients and limiting the use of Iressa only to those tumors having specific molecular signatures indicating a key contribution of EGF-R to disease pathogenesis. A second, related consideration derived from the possible contribution of other mutant proteins to the mitogenic and anti-apoptotic signaling operating in tumor cells; here again, these factors were not assessed. There is evidence, for example, that PTEN-negative tumors (which have a hyperactive PI3 kinase pathway; see Section 6.6) do not respond to Iressa, and that inhibitors of Akt/PKB (the downstream beneficiary of PTEN inactivation) can act synergistically with Iressa to halt tumor growth. Third, relatively few pre-clinical studies were undertaken in order to optimize the dosage and the schedule of treatments with this drug.

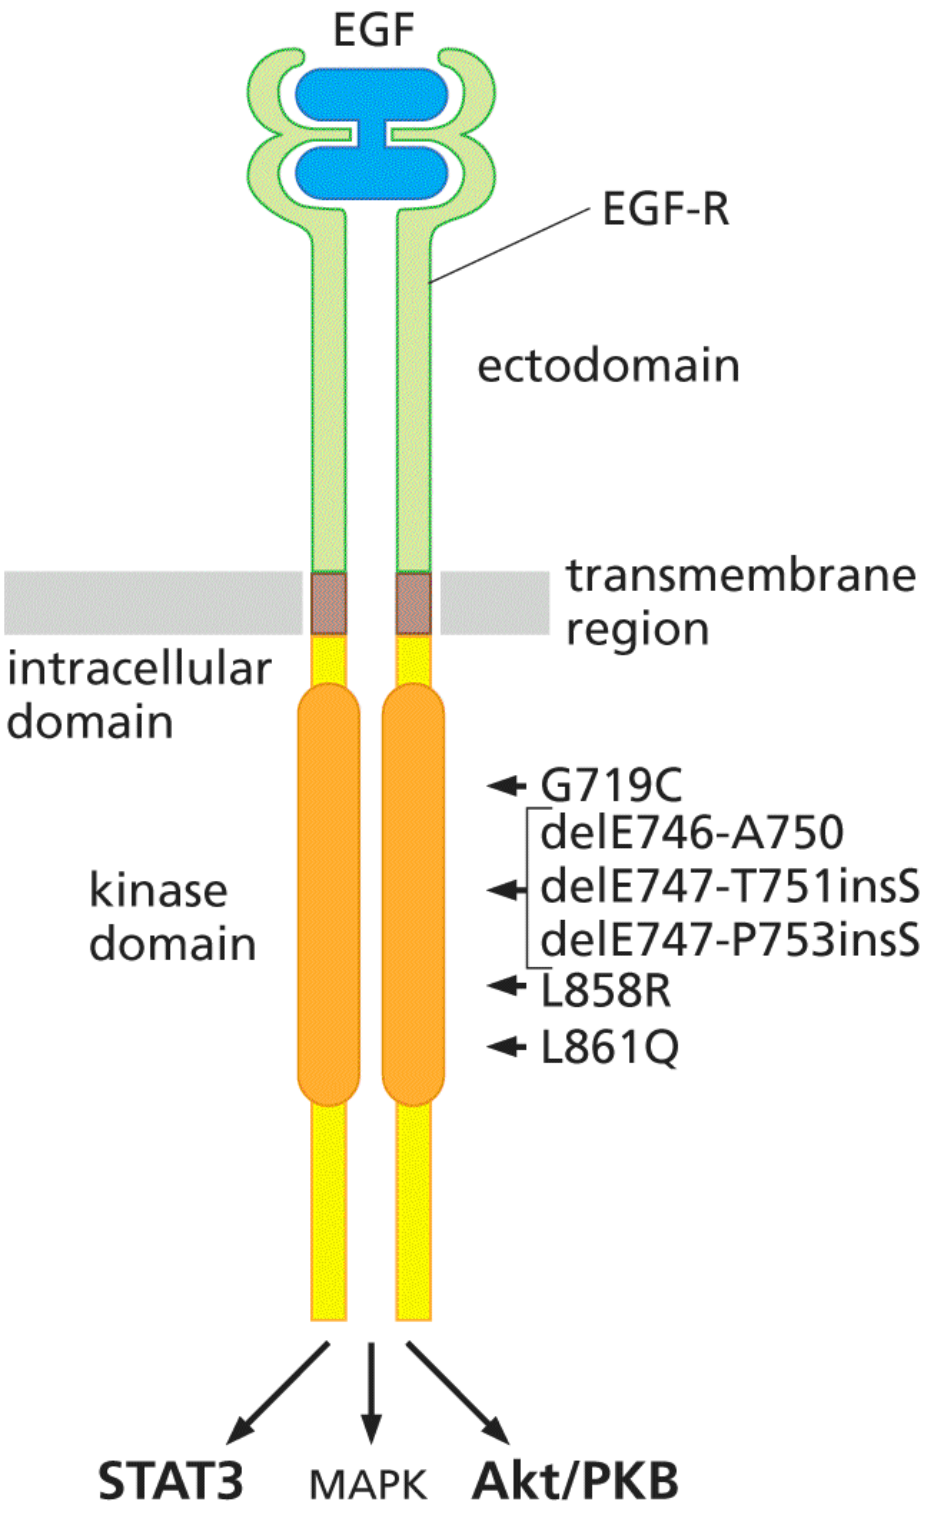
In 2004, four years after results of the initial clinical trials with Iressa were first reported, two research collaborations in Boston independently provided a molecular explanation for the observed responses to Iressa. Previously, the status of the EGF receptor in NSCLC cells was assessed by determining whether it was overexpressed and whether it was present in truncated, constitutively active form, as is the case in human glioblastomas. In the 2004 studies, however, investigators undertook detailed sequencing of the reading frames of the EGF-R–encoding gene in the NSCLC patients who had been treated with Iressa.

Quite dramatically, they found that almost all of the small group (~10% of the total) of NSCLC patients who had responded well to Iressa treatment (**Figure 17.37A**) bore tumor cells displaying structurally altered EGF-Rs. Such mutant receptors were not found among the tumors that failed to respond to Iressa, including those that expressed elevated levels of this receptor (see, for example, **Supplementary Sidebar 17.9**). For example, 78% of patients who responded to anti-EGF-R therapy expressed mutant EGF-R protein, whereas among the nonresponders only 6% showed such structurally altered receptor proteins.



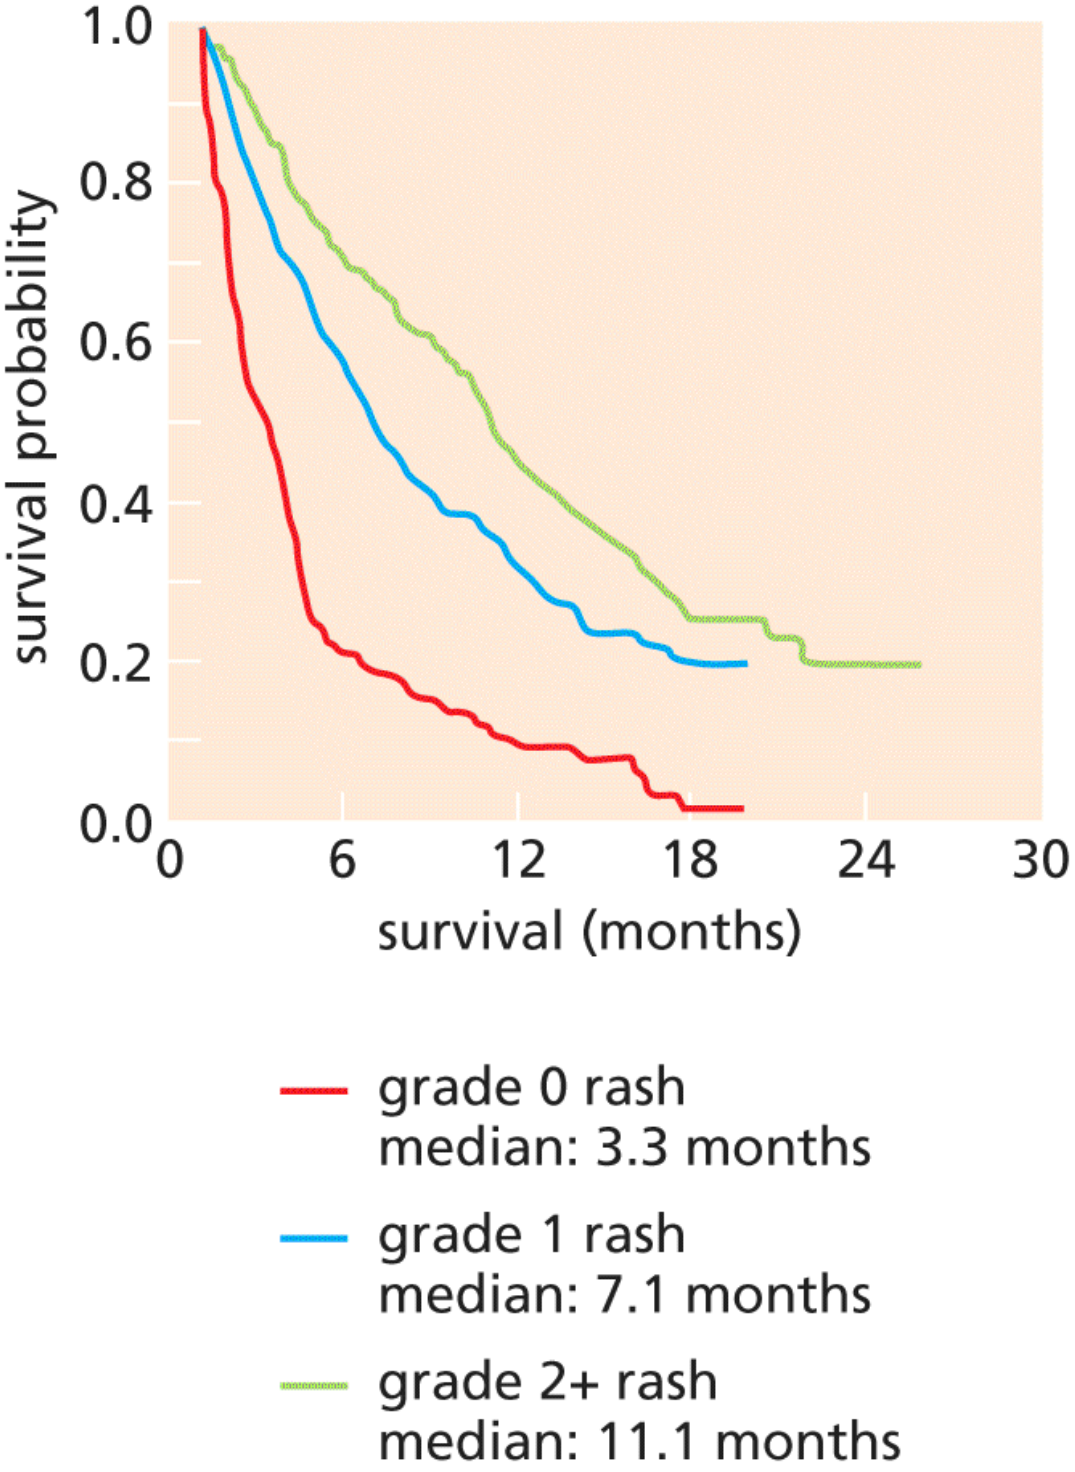
Two computerized tomographic images show a large mass in a lung. The first image shows a healthy black lung on the the right. The lung on the lefts is mostly filled with a large white mass. Six weeks after treatment with Iressa, the area that was completely white is now black and dark gray.

(A)



A diagram of a E G F R receptor embedded in a cell membrane. The ectodomain consists of an E G F binding site where E G F is currently bound. The intracellular domain contains a kinase domain and ultimately stimulates STAT 3, MAP K, and A k t slash P k B. Different deletions and point

mutations are listed next to the kinase domain. The point mutations are G 719 C, L 858 R, and L 861 Q. The deletions are from E 746 to A 750, from E 747 to T 751 ins S, and from E 747 to P 753 ins S.
(B)



A graph shows the relationship between the appearance of rashes and survival probability. For those that have a grade 0 rash, the median survival is 3.3 months. By 19 months, the survival probability is 0. For those that have a grade 1 rash, the median survival is 7.1 months, By 19 months, the survival probability is 0.2. For those that have a grade 2 plus rash, the median survival is 11.1 months. By 24 months, the survival probability is 0.2.

(C)

Figure 17.37 Determinants of responsiveness of NSCLCs to Iressa and Tarceva treatment (A) A minority of patients with refractory non-small-cell lung cancers (NSCLCs)—tumors that failed to respond or ceased to respond to standard chemotherapy—show dramatic responses to treatment by Iressa. These computerized tomographic images reveal dramatic regression of a large mass (*left*) in a patient's right lung following six weeks of Iressa treatment (*right*). (B) A substantial proportion of NSCLCs that respond to Iressa have been found to carry deletions ("del") and point mutations in the EGF-R gene that affect the cytoplasmic domain of the receptor. These alterations in EGF-R structure deregulate and activate the tyrosine kinase function of the receptor, thereby stimulating the Akt/PKB and STAT signaling pathways, which protect these tumor cells from apoptosis (see Figures 6.10 and 6.16). (C) Experience with a variety of anti-EGF-R treatments has indicated that, in addition to the genetic state of the tumor cells, the development of an acne-like rash by patients under treatment is a strong positive indicator of the eventual response of tumors to therapy. (This response clearly reflects the role of the EGF-R in skin keratinocyte biology and the precise mechanistic connection between the normal keratinocyte response of patients to therapy and the response of their tumors remains obscure.) In this case, the responses of NSCLC patients to Tarceva therapy are shown in this Kaplan–Meier graph. "Median" indicates median survival. (A and B, from T.J. Lynch et al., *N. Engl. J. Med.* 350:2129–2139, 2004. With permission from Massachusetts Medical Society. C, from B. Wacker et al., *Clin. Cancer Res*. 13:3913–3921, 2007. With permission from American Association for Cancer Research.)

The mutations found in the altered EGF-Rs created amino acid substitutions and small deletions in the kinase domain (Figure 17.37B) rather than the major deletions of the receptor ectodomain typically found in glioblastomas. These mutant receptors showed distinctive patterns of tyrosine phosphorylation of their C-terminal tails (see Section 6.3) and selectively stimulated the downstream Akt/PKB and STAT5 pathways, leaving the MAPK signaling pathway unaffected.

These observations provided compelling evidence that the EGF-R played a central role in driving the growth of these small groups of tumors. In addition, they demonstrated

the value of stratification of tumors using molecular markers when treating patient populations with targeted molecular therapeutics such as Iressa and Tarceva. Still, these experiments did not reveal why Iressa and Tarceva had such strong effects on these particular tumors (**Sidebar 17.14**).

Sidebar 17.14 Oncogene addiction may explain how Iressa and Tarceva succeed in killing NSCLCs

The mutant EGF-Rs that are found in certain NSCLCs cause the cells from these particular tumors to be approximately 100 times more sensitive to Iressa than tumors expressing the wild-type receptors (Figure 17.31A). Importantly, the actual drug concentrations in the plasma of patients being treated fall in the range that allows such selective inhibition to operate. The mechanism of oncogene addiction, introduced in Section 17.4, may explain the selective effects of both Iressa and Tarceva on tumors expressing structurally altered EGF-Rs. Recall that oncogene addiction refers to the strict dependence of certain cancer cells on a certain oncogene or oncoprotein for their growth and survival, whereas other types of cancer cells can lose this gene or protein without suffering significant consequences.

To explain this behavior, we can imagine that some oncogenes are generally deleterious when expressed in wild-type cells but are actually beneficial in cells that previously acquired certain mutant alleles of another oncogene. A good example is provided by the *myc* oncogene, which has pro-apoptotic effects on cells unless they are protected from apoptosis by an acquired anti-apoptotic allele of some sort (for example, a *ras* oncogene); in the presence of the anti-apoptotic mutation, the strongly mitogenic effects of the *myc* oncogene then become apparent. Hence, tumor cells that carry both the *ras* and *myc* oncogenes would behave as if they were “addicted” to the *ras* expression, because they would die quickly by apoptosis if they were deprived of the *ras* oncogene.

Similarly, early in tumor progression, the acquisition of a certain oncogene, such as a mutant EGF-R gene, might create a cellular environment that permits acquisition of other oncogenes (or losses of tumor suppressor genes) that would, on their own, be highly deleterious for tumor cells. If the mutant receptor is now lost, then the deleterious effects of these other oncogenes, such as those favoring apoptosis, would become apparent and result in rapid loss of cell viability.

In the case of non-small-cell lung cancer (NSCLC), those tumors bearing mutant receptors may have come to depend on the firing by their mutant EGF-Rs in order to survive and proliferate; that is, they are “addicted” to the mutant receptors. Conversely, the far more numerous NSCLCs expressing the wild-type EGF-R, often at elevated levels, may have developed alternative means of securing mitogenic and

survival signals, as is indeed suggested by the observation of receptor-independent firing of the MAPK and PI3K pathways in some lung cancers.

This scenario is further supported by experiments using siRNAs to inhibit the expression of wild-type or mutant receptors (see **Supplementary Sidebar 1.5**): NSCLC cells with mutant EGF-R die quickly, whereas those displaying wild-type receptor are only slightly affected (see Figure 17.31B and C). Consequently, the death of cancer cells with mutant EGF-Rs does not occur from some unknown, off-target effect of Iressa or Tarceva, but instead is caused directly by the loss of beneficial signals released by these receptors. Moreover, experiments like these suggest that EGF-R inhibitors may have far greater effects on NSCLCs expressing wild-type receptors if they are applied together with a second drug that inhibits another, functionally redundant signaling pathway, such as the one controlled by PI3K.

An additional puzzle comes from the frequency of the NSCLCs found to express the structurally altered EGF receptors. They have been found in the tumors of ~10% of Western patients suffering from NSCLC, although in certain Asian populations, as many as 30% of the NSCLCs analyzed express these mutant receptor proteins; these altered EGF receptors would appear to explain the far higher response rates to Iressa in Japan cited above. (In all cases these altered receptors result from somatic mutations rather than inherited germ-line alleles.) The reasons for these inter-ethnic discrepancies and the greater frequency of these tumors in female nonsmokers represent additional puzzles.

One mystery seems to have been solved, however. In certain East Asian populations, as many as half of CML patients show an incomplete response to Gleevec therapy compared with only one-fourth of Western patients; a similar therapy-resistant subpopulation exists among NSCLC populations and their responses to EGF-R inhibitors. In both cases, the patients' tumors are resistant from the beginning of treatment to the effects of the tyrosine kinase inhibitors (TKIs) used to treat these two diseases. Among oncologists, this preexisting resistance is often called primary resistance to distinguish it from the resistance that develops during the course of therapy, which is termed secondary resistance.

In both NSCLC and CML, primary resistance has been traced to an allele of the pro-apoptotic *Bim* gene (see Section 9.13) that encodes a defective version of the Bim protein and is carried by 12.3% of East Asians but is absent in African and European populations. Other work has shown that expression of the wild-type Bim protein is suppressed by oncogenic tyrosine kinases, and its activation following TK inhibition contributes importantly to the apoptotic cancer cell death that drugs like Gleevec, Iressa, and Tarceva succeed in inducing in responsive cell populations. Lacking both copies of the wild-type *Bim* gene and thus normal levels of the Bim protein, the tumors

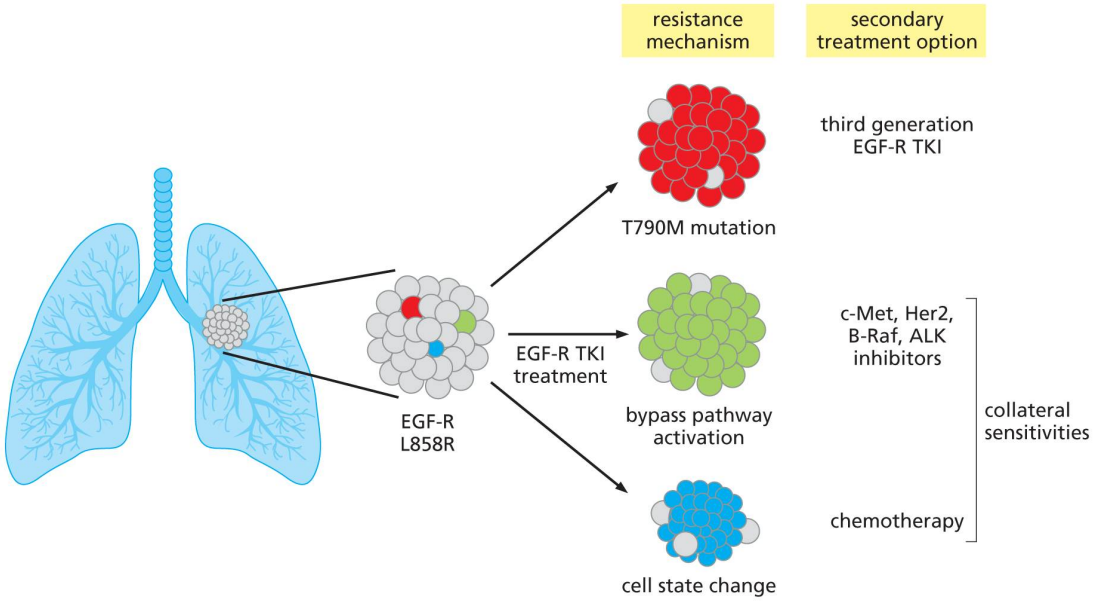
of these East Asian patients show substantially reduced tendency to enter into apoptosis and thus reduced responsiveness to the killing effects of these inhibitors.

In addition to the germ-line and somatically acquired alleles cited above, there are yet other indications that are useful for predicting responsiveness to anti-EGF-R TKIs. Echoing the results from use of anti-receptor MoAbs (see **Supplementary Sidebar 17.9**), the presence of a mutant, activated K-*ras* or *PI3K* oncogene or an inactivated *PTEN* tumor suppressor gene is strongly correlated with the failure of tumors to respond to these TKIs. These findings can all be rationalized in terms of the signal transduction cascades that we encountered in Chapter 6. Thus, if a downstream cytoplasmic effector of a cell surface receptor becomes activated by mutation, its firing no longer depends on the upstream receptor and can continue unabated, even if the receptor itself is inactivated, in this case by targeted therapies.

There is, however, a striking finding that cannot be rationalized in terms of our current understanding of cellular signaling and therefore represents an abiding mystery: the best surrogate marker of a tumor's responsiveness to various anti-EGF-R therapies is the development by the cancer patient of a readily observable severe skin rash (see Figure 17.37C). Because the skin is clearly not involved in the pathogenesis of lung and colorectal carcinomas, this rash might mean that there exist significant inter-individual differences in pharmacokinetics (PK) that determine therapeutic outcome and, in parallel, affect the skin; in truth, however, there is no correlation between PK and skin rash development. In addition, the positive correlation between skin rash severity and therapeutic response applies to a variety of low–molecular-weight drugs as well as anti-receptor monoclonal antibodies (see **Supplementary Sidebar 17.9**). These observations provide a strong indication that some subtle, inter-individual variability in the behavior of the basic signal-processing machinery operating in various epithelial cells throughout the body strongly influences responsiveness to anti-EGF-R therapies. This behavior reminds us of how little we understand about the regulators of cell signaling, whose behaviors are more than minor determinants of the success or failure of current, so-called rational therapies.

Unfortunately, even positive responses to these tyrosine kinase inhibitors have been short-lived, and most patients relapse in 6 to 18 months, having developed a secondary resistance to drug treatment. Acquired resistance to erlotinib and gefinitib can occur via a diverse set of mechanisms that highlight both the promise of new therapies as well as the fundamental challenges in achieving durable clinical responses, including cures. The first and most common mechanism of EGF-R inhibitor resistance is mutation of the receptor itself. The T790M amino acid substitution, the product of a so-called gatekeeper mutation, alters the ATP binding pocket of EGF-R (**Figure 17.38**). Rather than blocking drug interaction with EGF-R, this amino acid change increases the receptor affinity for ATP such that the effect of inhibitors is diminished. The common appearance of these mutations following treatment with first generation

EGF-R inhibitors led to the development of second and third generation EGF-R inhibitors that can target the T790M mutant. Drugs like osimertinib are now used in the treatment of T790M-mutant NSCLC. Because this agent can also target unmutated EGF-R, it is often used as a first-line therapy that can preempt the eventual emergence of T790M-mutant tumors.



A diagram shows different routes to resistance to E G F R inhibitors in a tumor in a lung. The tumor cells have an E G F R L 858 R mutation. The tumor is treated with E F G R T K I treatment. Three resistance mechanisms occur in different cells, each which replicate and make their own cluster of tumor cells. The first is a T 790 M mutation. The secondary treatment option is third generation E G F R T K I. The second resistance mechanism is bypass pathway activation. The secondary treatment options are c Met, Her 2, B Raf, and A L K inhibitors. The third resistance mechanism is cell state change. The secondary treatment option is chemotherapy. The second two resistance mechanisms are labeled as collateral sensitivities.

Figure 17.38 Routes to resistance to EGF-R inhibitors Non-small-cell lung cancers (NSCLC) driven by mutation and amplification of EGF-R are sensitive to EGF-R inhibitors including erlotinib and gefitinib. In this illustrated case, an L858R amino acid substitution in a mutant EGF-R drove initial outgrowth of the NSCLC. Resistance to EGF-R-inhibitory drugs could occur via a variety of alternative mechanisms (*middle column*), including second-site mutations in EGF-R (most frequently the T790M "gatekeeper" mutation, *red cells*), activation of parallel bypass pathways or downstream signal transducers (e.g., c-MET, Her2, ALK, or B-Raf activation, *green cells*), or cell state changes (e.g., EMT or transdifferentiation to small-cell lung cancer, *blue cells*). Each resistance state is,

in turn, targetable by a subsequent cancer therapy (*right column*). In the case of the activation of bypass pathways and cell state changes, these resistance mechanisms create "collateral sensitivities" or emergent sensitivities that were not present in the initial pre-treatment tumor. The existence of such emergent sensitivities presents opportunities for effective sequential cancer therapy, but also creates challenges in determining how and when such therapies should be applied.

A second, alternative mechanism of acquired EGF-R inhibitor resistance involves the activation of parallel growth signaling pathways. For example, the overexpression—often resulting from gene amplification—of the c-Met TK receptor can substitute for EGF-R signaling in treated tumor cells. Similarly, alterations in kinases downstream of EGF-R (see Section 6.5) can also promote cell survival in the face of EGF-R inhibition. Activating mutations in B-Raf kinase (discussed in Section 17.16 of this chapter), a downstream target of EGF-R signaling, can obviate the requirement for upstream EGF-R activity.

Finally, as mentioned earlier in the context of Bcr-Abl signaling, cell state changes can also promote resistance to EGF-R inhibitors. In one such example, NSCLCs have been shown to undergo an EMT-like switch to a more mesenchymal phenotypic state following treatment (see Sections 13.3 and 14.3). In another, treated NSCLC patients may suffer relapses concomitant with a shift in the phenotype of their tumors and tumor cells, suggesting their entrance into a state closely resembling that of small-cell lung cancer (SCLC), a tumor thought to have a developmental origin distinct from that of the more common adenocarcinomas. Precisely how this kind of developmental transition—essentially a transdifferentiation—occurs remains unanswered.

In all these cases, the specific resistance mechanisms that appear in relapsed tumors inform the choice of specific actionable therapies. Thus, T790 mutant tumors are treated with osimertinib; c-Met–amplified tumors are treated with c-Met inhibitors combined with EGF-R inhibitors; B-Raf mutant tumors are treated with B-Raf inhibitors; and tumors that have undergone the cell state change described above are treated with chemotherapy, to which SCLC tumors respond much more effectively than do NSCLCs. This connection between resistance mechanisms and actionable therapeutic strategies designed to target resistance states represents a major advance in cancer therapy, one that has extended and improved the lives of cancer patients. However, none of these treatments is ultimately curative, highlighting the fundamental, ongoing challenge of drug resistance: while we have substantially increased our arsenal of agents to target a variety of tumor-associated alterations, tumor cells invariably contrive more alternative paths to resistance than we have drugs to treat them.

Glossary

partial response
: Halting of further tumor growth or a 50% or greater reduction in tumor mass following anti-cancer therapy. *See also* **complete response**.

primary resistance
: Term denoting the behavior of a tumor that is refractory to treatment from the onset of that treatment; *also termed* **intrinsic resistance**. *See also* **secondary resistance**.

secondary resistance
: Term denoting the behavior of a tumor that was initially responsive to a treatment but subsequently becomes refractory to that treatment; *also termed* **acquired resistance**. *See also* **primary resistance**.

gatekeeper
: (1) An oligopeptide domain that controls access by small molecules to the catalytic cleft of an enzyme such as a kinase. (2) A gene that operates to regulate cell proliferation or to regulate cell number by controlling cell differentiation or cell death. Loss of a gatekeeper gene removes an impediment to cell proliferation and thus to the appearance of populations of neoplastic cells. *Compare* **caretaker**, **tumor suppressor gene**.

transdifferentiation
: Transition by a cell from one differentiation lineage into the phenotypic state characteristic of cells from another, distinct differentiation lineage.

bronchoalveolar
: Subtype of lung adenocarcinoma usually arising in peripheral areas of the lung and referring to tissues derived from small airways termed bronchioles and associated alveoli. *See also* **alveolus**.

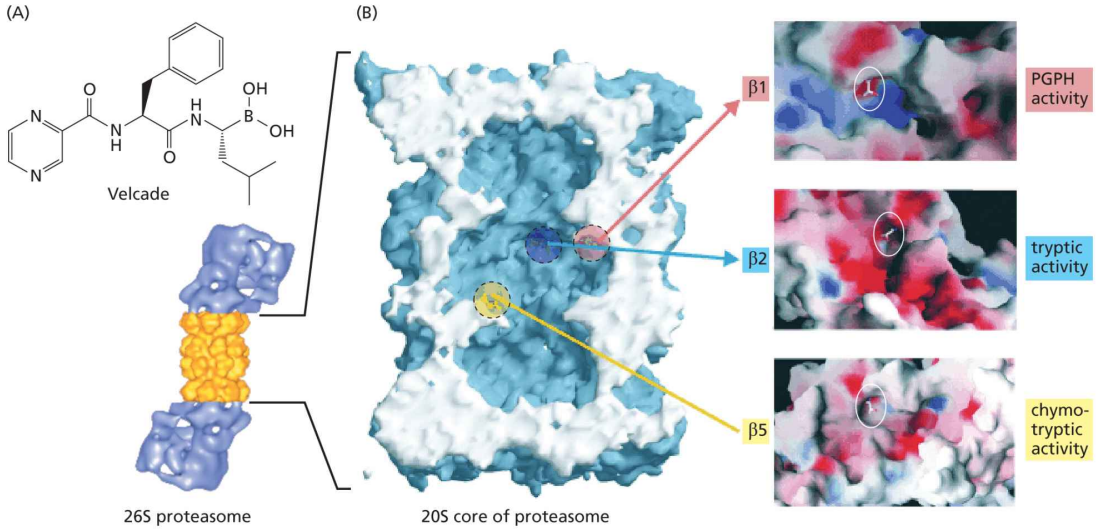
17.15 Proteasome inhibitors yield unexpected therapeutic benefit

Serendipity plays an unusually prominent role in the world of drug discovery. On occasion, the development of an anti-cancer drug is launched as part of a rational drug design program and ultimately yields an agent that turns out to be highly useful, albeit for reasons quite unrelated to those that inspired its development in the first place. This best describes the development of the drug known as Velcade, also called PS-341 and bortezomib (**Figure 17.39A**).



A two part figure about velcade and its effects on proteasomes. Part A. The chemical structure of velcade. It consists of a six membered chain with the atoms carbon, nitrogen, carbon, carbon, nitrogen, and carbon. The first carbon is bonded to a benzene ring where two of the carbons are replaced by nitrogen. The second and fourth carbons are part of carbonyl groups. The last carbon is bonded to another carbon side chain and a bromine atom that is further bonded to two hydroxyl groups. The third carbon in the initial chain is bonded to a carbon that is further bonded to a benzene ring. Part B. A 3 D rendering of a 26 S proteasome. The proteasome is shaped like an uneven cylinder with three sections. The middle section is the 20 S core. A cross-section reveals that it has three catalytic sites on the interior edge. The first is beta 1, which is responsible for the P G P H activity. The second is beta 2, which is responsible for the tryptic activity. The third is beta 5, which is responsible for the chymotryptic activity.

Figure 17.39 Velcade and its effects on proteasomes (A) The chemical structure of Velcade reveals the presence, unusual among drugs, of a boron atom. Peptide boronic acids like Velcade were known to bind to the active site of serine proteases of the chymotrypsin class (which cleave substrate proteins adjacent to phenylalanine and tyrosine residues) by mimicking the normal substrates of these enzymes. This finding suggested to the drug developers that such compounds might inhibit the chymotrypsin-like active site in the 20S core of the proteasome. (B) A cross section (*center*) through the central (20S) core of the yeast proteasome (*left*) reveals the locations of three distinct catalytic sites, involving the β1, β2, and β5 subunits of the proteasome (*far right*), which are responsible for its PGPH (peptidyl-glutamyl-peptide hydrolyzing), tryptic, and chymotryptic proteolytic activities, respectively. Velcade shows a strong preference for inhibiting the β5 chymotryptic activity (*lower right*); a weak interaction with the β2 tryptic activity (*middle right*); and no interaction with the β1 PGPH activity (*top right*). The key nucleophilic threonine residue in each of these catalytic sites is shown as a stick figure (*white inside white ovals*); basic amino acids in the catalytic clefts are in *blue*, acidic amino acids are in *red*, and hydrophobic residues are in *white*. (B, from M. Groll et al., *Chembiochem* 6:222–256, 2005. With permission from John Wiley & Sons.)

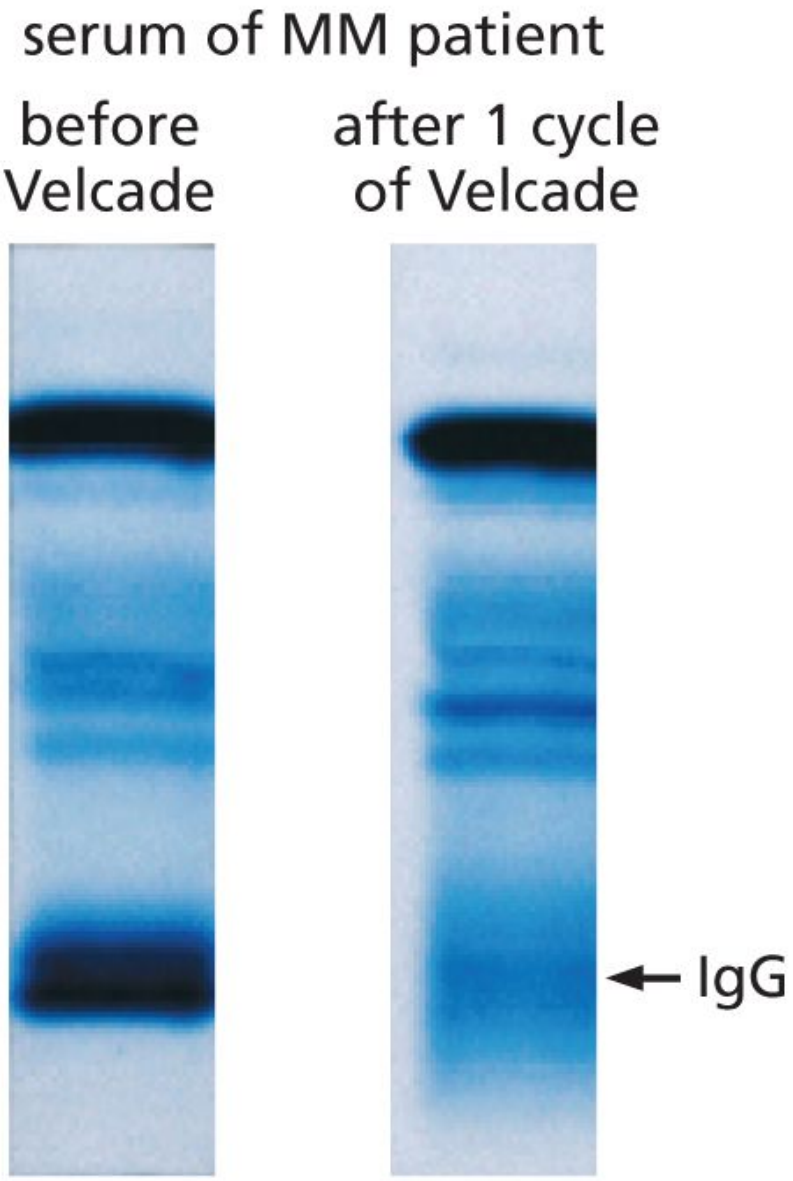
On many occasions throughout this book, we have seen how the levels of key cellular regulatory proteins are determined by the balance between their synthesis and their degradation. Much of this degradation is mediated by the ubiquitin–proteasome system (see **Supplementary Sidebar 7.5**). Recall that the tagging of a protein by polyubiquitylation results in its transport to proteasomes and its degradation in these intracellular machines.

The phenomenon of cancer-associated cachexia initially stimulated interest in inhibitors of proteasome function. Cachexia occurs late in tumor progression and represents a progressive wasting of the cancer patient's tissues through mechanisms that remain poorly understood. It was speculated that a proteasome inhibitor could be useful in retarding the widespread degradation of proteins occurring in the tissues of cachectic patients. At least five distinct classes of proteasome inhibitors have been developed, although most have been abandoned as candidates for clinical use because of metabolic instability, lack of specificity, or irreversible binding and inactivation of proteasomes.

Velcade, one of these proteasome inhibitors, is a boronic acid dipeptide that was designed as a specific inhibitor of the peptidase (peptide-cleaving) activity that occurs in the 20S core of the proteasome (Figure 17.39B). It has extraordinary potency, being able to inhibit 50% of the proteasome's chymotryptic activity at a concentration (that

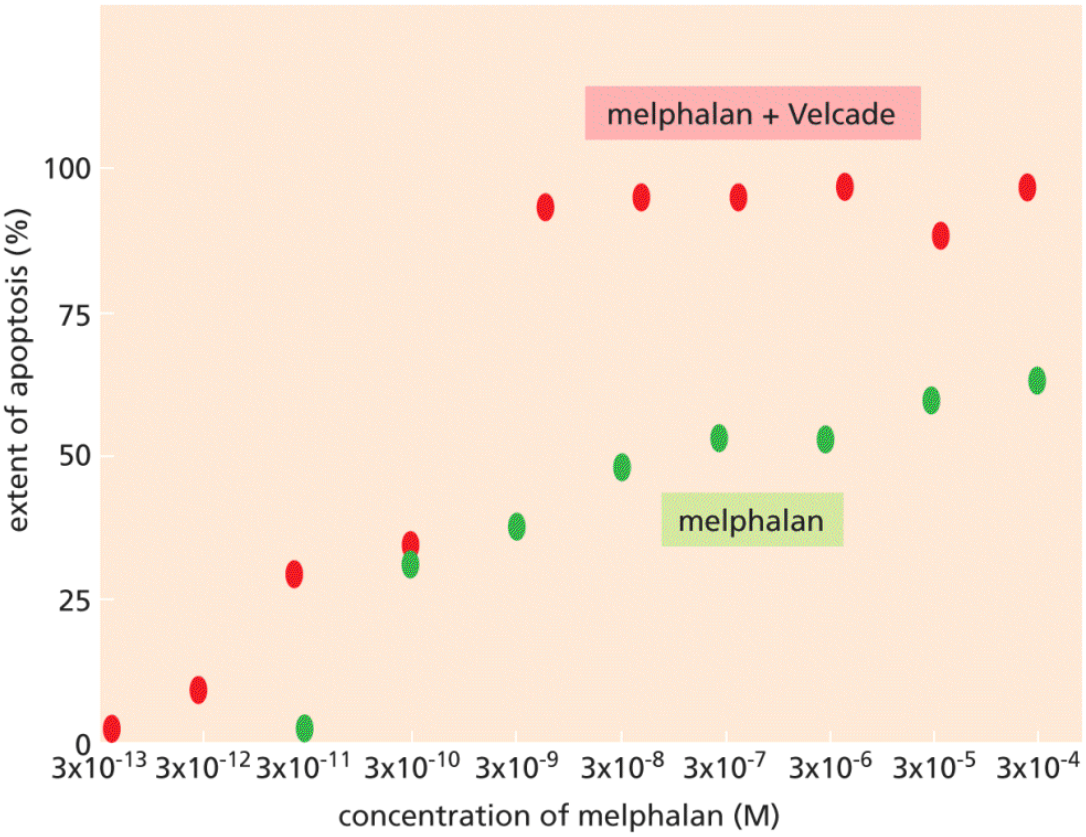
is, its K_i) of only 0.6 nM. Functioning as a competitive inhibitor of this enzyme activity, Velcade slows the flux of substrates through proteasomes, which soon become clogged and dysfunctional.

Proteasome-mediated degradation was subsequently found to play a critical role in regulating a number of key cellular signaling pathways. Because other proteasome inhibitors had been found to be especially potent in killing a variety of cultured cancer cells, Velcade was used in Phase I trials to treat cancer patients who had failed other available therapies. Those with solid tumors showed few striking responses. However, among a group of patients with hematological malignancies was an individual suffering from multiple myeloma (MM), a malignancy of the B-cell lineage in which a single clone of antibody-producing plasma cells undergoes clonal expansion and ultimately dominates the bone marrow. The myeloma cells create osteolytic bone lesions that lead to fractures, and they ultimately crowd out the remaining cellular components of the marrow, resulting in severe immune depression and, typically, death from overwhelming infection. Survival after initial diagnosis is usually three to five years. The myeloma carried by this initially treated patient showed a dramatic regression (**Figure 17.40A**), which soon led to the inclusion of other myeloma patients in this Phase I trial and eventually to large-scale clinical trials.



Two gel electrophoresis images from the serum of an M M patient before and after 1 cycle of Velcade treatment. Both gels have multiple dark bands. The band corresponding to I g G is much darker before Velcade treatment than it is after treatment.

(A)



A scatterplot shows the percent extent of apoptosis relative to the concentration of melphalan when used with and without Velcade. The concentration of melphalan ranges from 3 times 10 to the negative 13 molar and 3 times 10 to the negative 4 molar. Percent extent of apoptosis increases as the concentration of melphalan increases. With melphalan only, the extent of apoptosis never exceeds 70 percent. However, when combined with Velcade, the percent of apoptosis is close to 100 percent for concentrations of 3 times 10 to the negative 9 to 3 times 10 to the negative 4.

(B)

Figure 17.40 Multiple myeloma and the biological effects of Velcade (A) Velcade can have profound effects on the cellular contents of the marrow and thus the composition of antibody molecules in the blood. In one multiple myeloma (MM) patient, after eight doses of Velcade, the neoplastic plasma cells in the marrow declined from 41% of total cells to 1%. At the same time, the level of the single species of immunoglobulin γ (IgG) made by these myeloma cells declined drastically. As seen here, upon gel electrophoresis, the small number of IgG species present before treatment (indicative of the homogeneous antibody population produced by a monoclonal tumor, *left*) resolved into the heterogeneously migrating pattern of IgGs that are present in the circulation of a

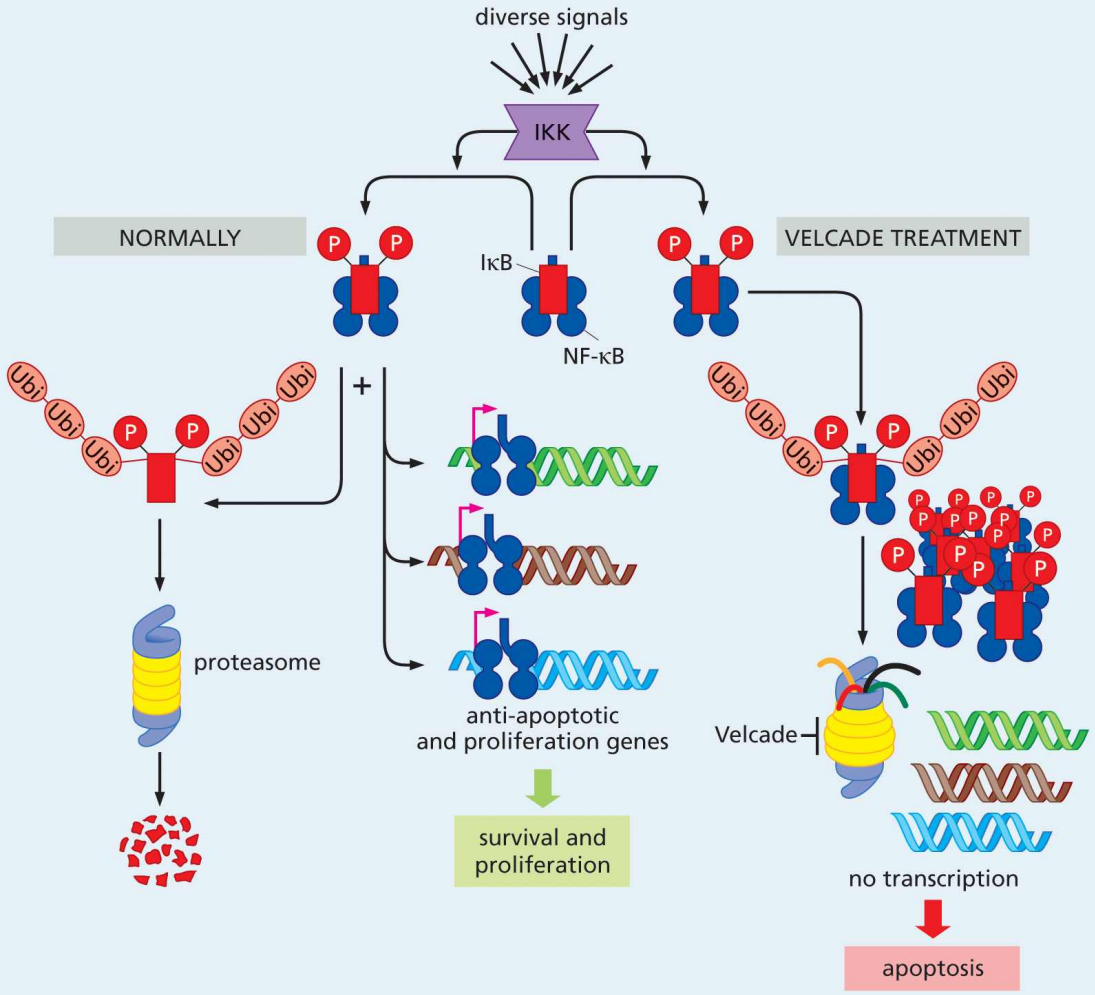
healthy individual (*right*). (B) Melphalan, an alkylating chemotherapeutic drug used routinely to treat MM, was added at various concentrations to an MM cell line *in vitro*, either on its own (*green*) or in the presence of a noncytotoxic dose of Velcade (*red*). In the presence of Velcade, melphalan was able to induce widespread apoptosis at approximately 3 nM concentration, but when applied on its own, melphalan was unable to induce this degree of apoptosis, even at vastly higher concentrations. (A, from R.Z. Orlowski et al., *J. Clin. Oncol*. 20:4420–4427, 2002. With permission from American Society of Clinical Oncology. B, from M.H. Ma et al., *Clin. Cancer Res*. 9:1136–1144, 2003. With permission from American Association for Cancer Research.)

In a subsequent Phase I clinical trial with a group of multiple myeloma patients suffering from rapidly progressing disease, Velcade showed clear "objective responses" in slowing disease progression in 55% of the patients and halted progression in another 25%. In a Phase II clinical trial, half of patients were given Velcade while the other half, who served as controls, were given dexamethasone, a standard treatment for multiple myeloma. Most of these patients had already failed the chemotherapies commonly used for myeloma. This trial was stopped prematurely in 2003 because Velcade demonstrated a clear superiority over existing treatments, with the disease showing a complete response in a small number of patients (that is, myeloma cells disappeared completely from the blood for at least six weeks) and a partial response (at least 50% reduction in myeloma cell–secreted antibody in blood and 90% reduction of this protein in urine over the same time period) in 35% of the Velcade-treated patients. As a consequence, the control patients were then allowed to take the drug as well. In a subsequent trial, the progression of myeloma to a higher stage of disease occurred with a median time of seven months in Velcade-treated patients compared with three months in a control group studied in parallel. Moreover, pre-clinical studies indicate that relatively low doses of Velcade can sensitize myeloma cells to chemotherapeutic drugs, making the latter far more effective (Figure 17.40B and **Sidebar 17.15**).

Sidebar 17.15 Myelomas as an attractive target of proteasome inhibitor therapies

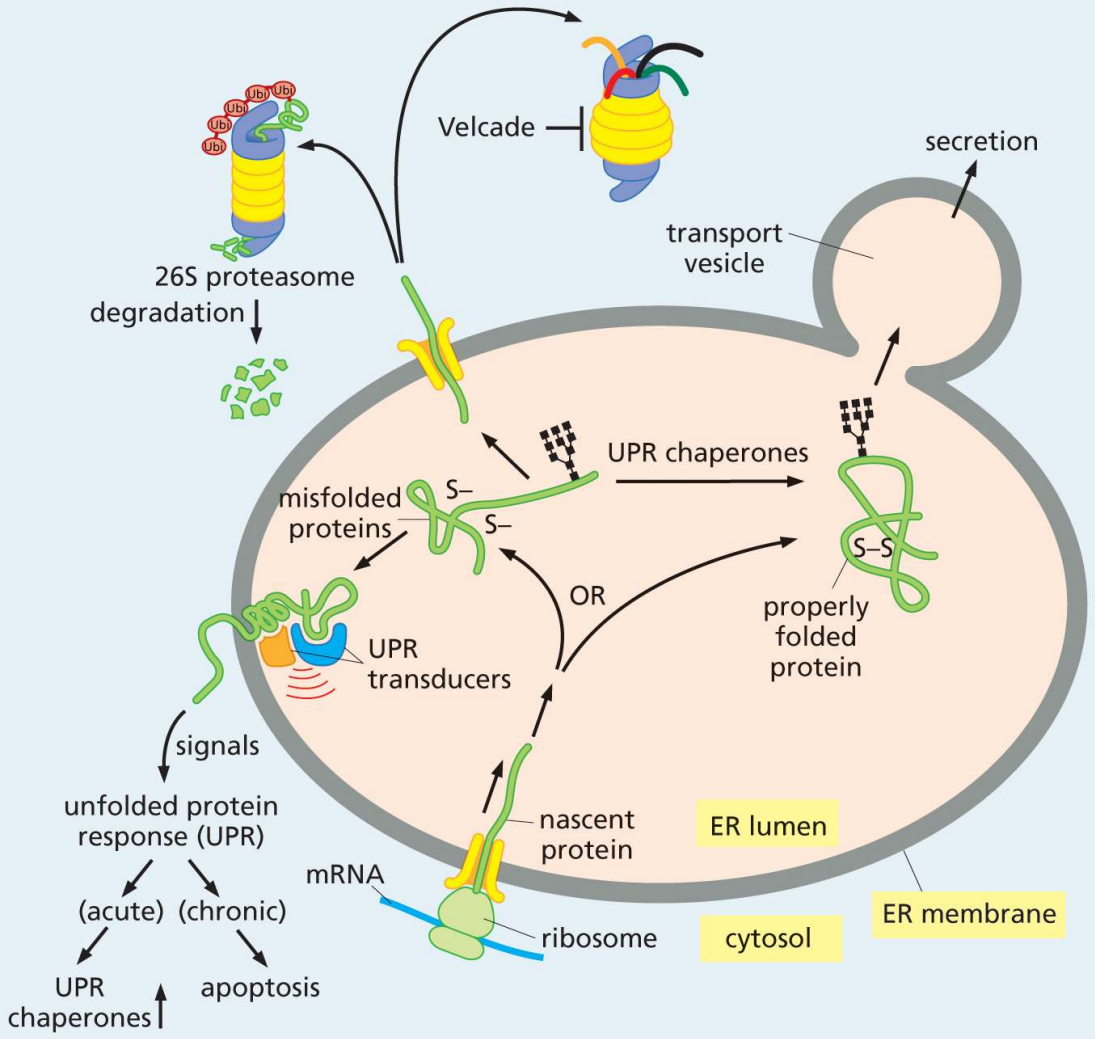
Inclusion of a myeloma patient in the initial clinical trial involving Velcade was hardly accidental. Multiple myeloma was thought to be an attractive target for treatment by a proteasome inhibitor because of the known elevated activity of the NF-κB signaling pathway in the myeloma cells and its physiological importance in driving the survival and proliferation of these cells. In Section 6.12 we noted that NF-κB transcription factors are normally sequestered in the cytoplasm by a class of inhibitors termed IκBs (inhibitors of N-κB). When these IκBs are phosphorylated by a group of specialized kinases termed IκB kinases, or simply IKKs, the IκBs undergo polyubiquitylation and

resulting degradation; this liberates the NF-κBs, allowing them to migrate into the nucleus, where they activate a number of anti-apoptotic genes as well as growth-promoting genes (**Figures 17.41 and 17.42**; see also Figures 6.22A and 11.38B).



A diagram shows the difference between the normal signal pathway and the pathway after velcade treatment. In both, diverse signals activate I K K. The I K K then phosphorylates I kappa B that is attached to N F kappa B. Normally, these two separate. I kappa B then is ubiquitylated and degraded in a proteasome. N F kappa B activates anti-apoptotic and proliferation genes, which leads to cell survival and proliferation. When there is velcade treatment, I kappa B and N F kappa B stay together. I kappa B is ubiquitylated, and Velcade then inhibits the proteasome. There is no free N F kappa B, so no transcription of the genes occur. This leads to apoptosis.

(A)

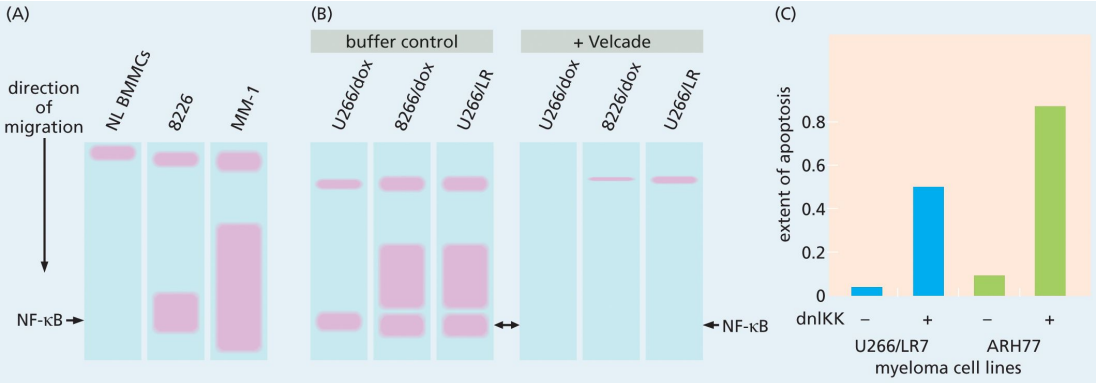


A diagram of the E R lumen showing pathways of proteins. m R N A in the cytosol is translated by a ribosome and the nascent protein enters the E R lumen. If the protein folds properly, it is secreted through a transport vesicle. If the protein is misfolded, three things may happen. One, U P R chaperones may correct the misfolding, turning it into a properly folded protein. Two, the misfolded protein may bind to a U P R transducer that signals an unfolded protein response. When acute, this leads to an increase in U P R chaperones. When chronic, this leads to apoptosis. Three, the misfolded protein may leave the E R and be degraded by a 26 S proteasome. However, if velcade is present, it inhibits the proteasome.

(B)

Figure 17.41 Mechanisms of Velcade action Two alternative mechanisms of action of Velcade have been proposed, and both are supported by extensive observations. (A) In normal and neoplastic cells (*left*), a variety of stress,

mitogenic, and trophic (survival) signals activate IκB kinase (IKK; *purple*, *above*, see Figure 6.22A). Once activated, IKK phosphorylates IκB (*red*), the inhibitor of NF-κB. This causes IκB to become ubiquitylated (*left*) and degraded in proteasomes (*lower left*). NF-κB (*blue*) is then free to move into the nucleus, where it activates the expression of numerous proliferation and anti-apoptotic genes. In the presence of Velcade (*right*), the ubiquitylated IκB cannot be degraded in the proteasomes because the latter have become engorged with unprocessed polypeptides. The IκB that accumulates in the cytoplasm binds and sequesters NF-κB (*right*). As a consequence, NF-κB is prevented from moving into the nucleus and activating expression of key anti-apoptotic genes. (B) The striking toxicity of Velcade for MM cells may arise because these cells, like normal plasma cells, are specialized to continuously synthesize and secrete enormous amounts of antibody molecules, in both cases on membrane-bound polyribosomes (*below, middle*). Like other secreted glycoproteins, antibody molecules are processed in the lumen of the endoplasmic reticulum (ER) prior to being secreted via exocytosis (*upper right*). Inevitably, a certain proportion of recently synthesized antibody molecules are misfolded following their insertion into the lumen of the ER. In the absence of proper folding, many of these misfolded proteins are extruded from the ER and broken down, following ubiquitylation, in cytosolic proteasomes (*upper left*). However, when proteasome function is blocked by Velcade (*above*), misfolded proteins accumulate in the lumen of the ER and trigger the unfolded protein response (UPR). This complex program includes the induction of apoptosis when misfolded proteins accumulate to toxic levels (*lower left*). (B, adapted from Y. Ma and L.M. Hendershot, *Nat. Rev. Cancer* 4:966–977, 2004. With permission from Nature.)



Three parts show evidence supporting the importance of N F kappa B signalling in Velcade induced apoptosis. Part A. An electrophoretic mobility shift assay shows the presence of N F kappa B in three types of cells. N L B M M cells have no N F kappa B band. 8266 cells have a thick band. M M 1 cells have a very thick band that is about three times as thick as the 8266 cell’s band. Part B. An

electrophoretic mobility shift assay shows the presence of N F kappa B in three types of cells with and without Velcade treatment. U 266 slash dox cells have a small band when treated with the buffer control and no band when treated with Velcade. 8226 slash dox cells have a large band when treated with the buffer control and no band when treated with Velcade. U 266 slash L R cells have a large band when treated with the buffer control and no band when treated with Velcade. Part C. A bar graph shows the extent of apoptosis in different myeloma cell lines. For the U 266 slash L R 7 cell line, extent of apoptosis was just above 0 for those that were d n l K K negative and around 0.5 for those that were d n l K K positive. For the A R H 77 cell line, extent of apoptosis was just around 0.1 for those that were d n l K K negative and around 0.9 for those that were d n l K K positive.
Figure 17.42 Evidence supporting the importance of NF-κB signaling in Velcade-induced apoptosis The scheme presented in Figure 17.41A is supported by a number of lines of evidence. (A) In an electrophoretic mobility shift assay (EMSA; also called a gel retardation assay), the presence and concentration of a functional, DNA-binding transcription factor (TF) are assessed by mixing an extract of nuclear proteins with a radiolabeled dsDNA oligonucleotide that carries a binding site for the TF. The presence of the DNA-binding TF is reflected by the amount of oligonucleotide that has formed a nucleoprotein complex with the TF; the large mass of protein associated with the oligonucleotide retards its migration during electrophoresis, causing it to migrate to a characteristic higher position in the gel. The arrow (*left*) indicates the expected location of a complex containing the NF-κB transcription factor and the radiolabeled oligonucleotide, in this case one derived from the promoter of the TNF-α gene, a target of NF-κB activation. (In the absence of bound DNA, the oligonucleotide migrates beyond the bottom of the gel.) The assay indicates little if any detectable NF-κB activity in normal bone marrow mononuclear cells (NL BMMCs, *left channel*), considerable activity in a multiple myeloma (MM) cell line (8226), and an enormous amount of NF-κB activity in the bone marrow cells prepared directly from a multiple myeloma patient (MM-1, *right channel*). (B) An EMSA has been used, as in panel A, to measure the level of functional NF-κB transcription factor in three MM cell lines treated with a control buffer (*left three channels*) or with Velcade (*right three channels*). Velcade eliminates essentially all NF-κB activity in these cells. (C) The importance of ongoing NF-κB signaling to the survival of MM cells is demonstrated by this experiment, in which a vector expressing a dominant-negative IKK (dnIKK) has been introduced into two different MM cell lines. If NF-κB signaling were critical to the action of Velcade, then the dnIKK should mimic the effects of Velcade by inducing MM cell apoptosis—the outcome that is indeed observed here. A vector that does not express dnIKK was used as control here. (From M.H. Ma et al., *Clin. Cancer Res*. 9:1136–1144, 2003. With permission from American Association for Cancer Research.)

Like myriad other polyubiquitylated proteins, the IκBs end up being degraded in proteasomes. Hence, by inhibiting proteasome action, IκBs should be protected from degradation, survive in the cytoplasm, and continue to sequester the NF-κBs, thereby blocking NF-κB nuclear translocation and activation of transcription. Nuclear, functionally active NF-κB was known to be important for inducing the expression of IL-4 and IL-6, two interleukins that operate as important autocrine factors required for the growth and survival of myeloma cells. In addition, as was learned later, NF-κB plays a prominent role in anti-apoptotic signaling in a number of cancer cell types; hence, loss of active NF-κB might well tilt the signaling balance within these cells toward apoptosis. More specifically, once cancer cells lose the potently anti-apoptotic Bcl-2, cIAP-2, and XIAP proteins (all of whose expression is induced by NF-κB), they are in grave danger of slipping into the apoptotic abyss.

All this does not explain, however, why Velcade is far more potent against myelomas than other tumors that rely on NF-κB signaling to protect them from apoptosis. A possible clue comes from observations that the growth and viability of myeloma cells is highly dependent on their ability to synthesize VEGF (vascular endothelial growth factor; see Section 13.1) and adhesion molecules; the latter enable myeloma cells to attach to bone marrow stem cells (BMSCs), with which the myeloma cells establish critically important heterotypic interactions. The genes encoding these various proteins are all under NF-κB control.

NF-κB antagonists are likely to have utility for treating a number of other kinds of cancer as well. Recall that NF-κB plays a key role in the development of a variety of carcinomas (see **Supplementary Sidebar 11.12**) and may be required for the maintenance of these tumors once they are formed. For example, gene expression and tumor mutational analysis has revealed that many B-cell lymphomas have constitutively activated NF-κB activity. Consequently, these tumors become attractive targets for treatment by either Velcade or a NF-κB treatment, and for one treatment-refractory B-cell lymphoma type, mantle cell lymphoma, Velcade now represents an effective therapy for many patients. However, other B-cell lymphoma types that have constitutive NF-κB signaling fail to respond to Velcade, suggesting that this tumor dependency may not be the sole determinant of Velcade response.

A second, alternative theory of Velcade's mechanism of action, which also has numerous proponents, does not attribute its effects specifically to inactivation of the NF-κB signaling pathway. According to this proposed mechanism, myeloma cells, like normal antibody-secreting plasma cells, continuously synthesize and secrete antibody molecules at a prodigious rate—estimated to be thousands of molecules per second. A certain portion of these molecules are routinely degraded in the proteasomes because of misfolding or other mishaps occurring during their post-translational maturation. As seen in Figure 17.41B, in addition to proteasomal degradation, accumulation of unfolded and misfolded proteins in the endoplasmic reticulum (ER) creates the state of

ER stress, which in turn activates the unfolded protein response (UPR). This complex program depends on signaling by receptor-like UPR transducers that convey information of the presence of significant numbers of misfolded proteins in the lumen of the ER. One component of the UPR, active during acute episodes of ER stress, results in molecular chaperones being dispatched from the cytosol into the lumen of the ER in order to properly fold the aberrant proteins. Another part of the UPR program operates in response to chronic ER stress and triggers apoptosis. Myeloma cells are especially sensitive to inhibitors of protein degradation and become engorged with misfolded protein molecules, specifically subunits of antibodies. In some poorly understood fashion, the failure of proteasomal function in the cytosol triggers activation of the UPR within the ER, and under many circumstances, this results eventually in the activation of apoptosis. The truly amazing potency and therapeutic index of Velcade—killing myeloma cells at concentrations as low as 1 nM—may be explained by the highly specialized secretory phenotype of these cells.

The lack of a clear mechanism underlying Velcade efficacy has confounded attempts to identify biomarkers for drug response. The absence of biomarkers represents a challenge to clinicians in providing optimal treatment to patients, and it also represents a common challenge in determining how to pay for such treatments. Specifically, given the extraordinarily high cost of some cancer therapies, it can be difficult to justify paying for therapies that are not effective in most patients. In the case of EGF-R inhibitor treatment, the identification of the subset of patients likely to be responsive to therapy not only improved the treatment of such patients but also made the use of these treatments feasible from a cost-benefit perspective for insurance companies and government health agencies. A pragmatic solution was found in the context of Velcade treatment: European healthcare agencies reached an agreement with drug developers to pay for Velcade only when the treatment showed efficacy in specific patients. Whether such arrangements will become commonplace for cancer therapy remains unclear, but in the case of Velcade this arrangement was fundamental to broad clinical use of the drug.

OceanofPDF.com

Glossary

cachexia
: Physiological state, often seen late in cancer development, in which the patient loses appetite and suffers wasting of tissues throughout the body.

peptidase
: Peptide-cleaving enzyme.

chymotryptic
: Referring to proteolytic reaction similar to that of chymotrypsin that cleaves protein substrates adjacent to hydrophobic amino acids.

multiple myeloma
: *See* **myeloma**.

objective response
: Demonstration of clinical response to therapy as gauged by changes in progression-free survival, overall survival, time to progression, size of tumor, marked improvement in patient symptoms, or other measurable response to therapy.

ER stress
: Physiological stress in the lumen of the endoplasmic reticulum often triggered by misfolded or unfolded protein domains. *See also* **unfolded protein response**.

unfolded protein response
: A cell-biological program, which is the main source of ER stress, that is activated by the accumulation of unfolded or misfolded proteins in the lumen of the endoplasmic reticulum; this program halts further translation, induces synthesis of molecular chaperones, and, if unsuccessful in reducing the level of unfolded and misfolded proteins, induces apoptosis. *See* **ER stress**.

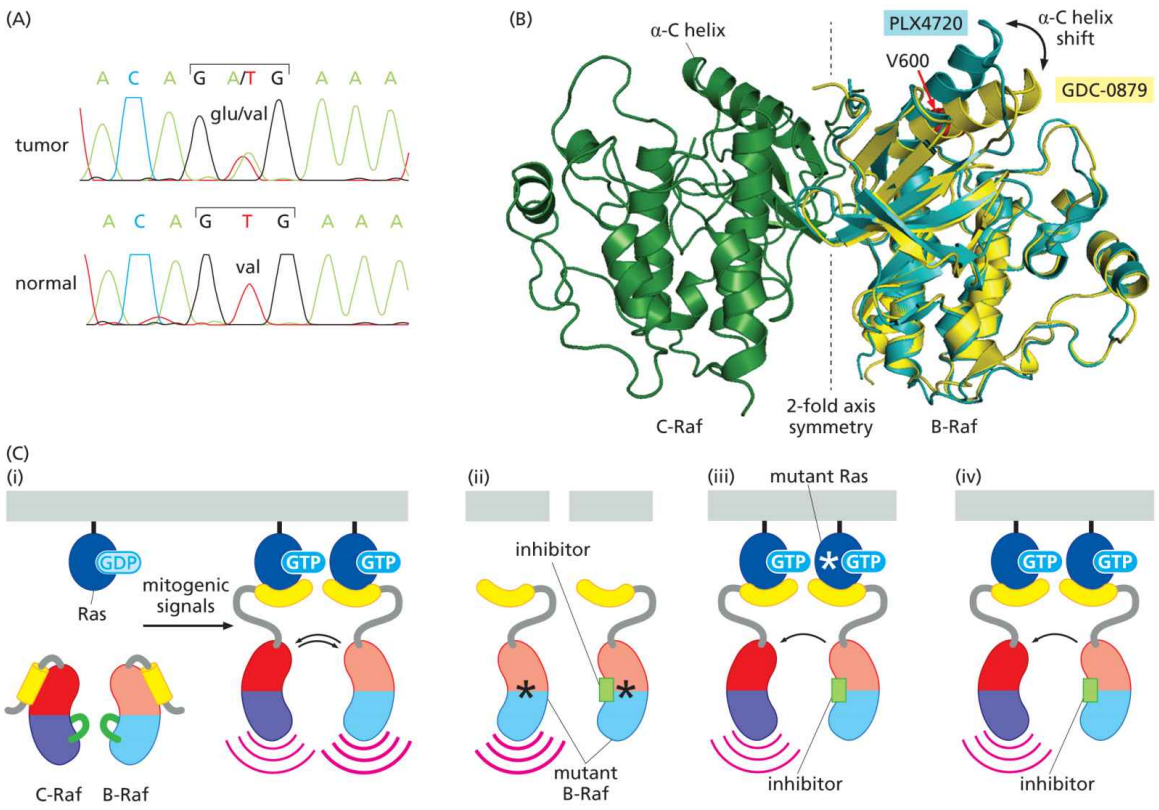
17.16 B-Raf discoveries have led to inroads into the melanoma problem

The sequencing of entire tumor cell genomes, made possible over the past decade by new technology, has uncovered large numbers of novel candidate oncogenes and tumor suppressor genes. However, the most important of these was actually found by focusing the sequencing technology on a known signaling pathway—exploring the well-lit ground under a familiar lamppost—the Ras–Raf–MEK–ERK pathway (see Section 6.5). Among other genes being studied was *C-Raf* (earlier called *Raf*) and its two paralogs, *A-Raf* and *B-Raf*, all of which are activated by GTP-bound Ras; *C-Raf* encodes the familiar Raf oncoprotein, first identified by its presence in an acutely transforming retrovirus (see Table 4.1). In 2002, sequence analysis revealed the presence of mutant *B-Raf* alleles in more than half of cutaneous human melanomas. In one sense, this was an astonishing finding, given that the Raf proteins, largely C-Raf, had been studied for two decades without there being any hint that one of these three genes was a frequent participant in the formation of a not-uncommon human malignancy.

Ninety percent of the mutant *B-Raf* alleles were found to carry point mutations in the codon encoding amino acid residue 600, causing a normally present valine to be replaced by a glutamic acid (**Figure 17.43A**). The behavior of this V600E mutation echoes that of the *Ras* oncogenes, in which an even greater proportion of mutant alleles affect a single codon, specifically codon 12 (see Figure 4.6). Interestingly, in melanomas and other tumor types, mutant *B-Raf* alleles are rarely found together with activated *Ras* oncogenes in individual cancer cell genomes; this mutually exclusive pattern indicates that the Ras–Raf–MEK–ERK pathway plays a key role in the development of these various tumors and suggests that these two classes of mutant alleles are functionally redundant.



A three part figure describes mutant B Raf and its treatment. Part A. The D N A sequences of a mutant tumor B Raf and a normal B Raf. The sequences are the same excep,t in the mutant, a T has changed to an A. This results in G A G, which codes for glutamine, versus G T G, which codes for valine. Part B. A ribbon model of the B Raf slash C Raf heterodimer. There is 2 fold axis symmetry, with the C Raf subunit on the left and the B Raf subunit on the right. Both sides have an alpha C helix pointing outward from the top. V 600 is near the base of this alpha C helix in B Raf. A mutation can cause the helix to shift positions. In one conformation, P L X 4720 binds, and in another conformation, G D C 0879 binds. Part C. A four part diagram shows different behaviors of Raf dimers in a cell. The first example shows C Raf, B Raf, and G D P bound Ras. After mitogenic signals, C-Raf and B-Raf each bind to a Ras that now has G T P bound. C Raf and B Raf are signalling. The second example shows that a mutant B Raf can signal without being bound to Ras. However, if an inhibitor is bound, it will not signal. The third example shows a C Raf bound to a Ras and a B Raf bound to a mutant Ras. The B Raf has an inhibitor. The B Raf activates signalling in the C Raf, but the B Raf is not signalling. The fourth example is the same as the third example, but the B Raf is bound to a normal Ras.

Figure 17.43 The mutant B-Raf and its treatment A search for mutant alleles of the genes controlling the main mitogenic signaling pathway in cells —the Ras–Raf–MEK–MAPK pathway—has revealed the frequent presence of mutant alleles of one of the three genes encoding Raf family kinases, which operate as serine/threonine kinases immediately downstream of the Ras proteins (see Figure 6.9A). (A) The discovery of point-mutated B-Raf alleles is shown here, in which sequencing of the genome of an ovarian tumor (*above*) revealed heterozygosity in codon 600 of the protein, which normally specifies valine (*below*). The mutant allele in the tumor genome was found to specify glutamic acid instead. This V600E mutant allele has since been found to be the predominant mutant B-Raf allele in more than half of all malignant melanomas and a variety of other tumors, including ~10% of colon carcinomas. (B) A molecular model of the B-Raf/C-Raf heterodimer structure is shown here. The two kinase molecules associate with one another in a parallel, side-to-side fashion, with residues from both the N- and C-terminal lobes contributing to the heterodimer interface. The V600 residue of B-Raf (*arrow, red*) is the most common structural alteration encoded by oncogenic mutations (usually V600E) and renders the enzyme constitutively active. Acting via allosteric interactions, the B-Raf protomer is able to activate C-Raf signaling even when B-Raf lacks kinase activity (as a result of mutation or drug action). The orientation of the α-C helices can affect B-Raf/C-Raf dimerization and thus C-Raf kinase activation. As seen here, the binding of two distinct B-Raf inhibitors, PLX4720 and GDC-0879, in the ATP-binding pocket of B-Raf shifts the orientation of this α-helix and thus the interactions between the two protomer subunits. (C) The behavior of Raf dimers greatly complicates the therapeutic effects of the B-Raf V600E inhibitor. (i) In normal cells, mitogen-activated GTP-bound Ras proteins bind and activate B-Raf/C-Raf heterodimers, with much of the downstream signaling being emitted by the more potent B-Raf partner; this results in activation of MEK and MAPK/ERK (see Figure 6.9A). (ii) In many melanomas, a mutant V600E B-Raf protein, acting in a Ras-independent fashion, can signal constitutively as a monomer (*right*), driving strong activation of this signaling cascade. A V600E-specific inhibitor (*green rectangle*) blocks this signaling (*right*), leading to temporary tumor regression of many melanomas. (iii) In cancer cells in which a mutant Ras oncoprotein is present (for example, in many colorectal carcinomas), the V600E-specific inhibitor, while shutting down B-Raf signaling, causes the latter to activate, via allosteric interactions, signaling by C-Raf. (iv) In certain normal cells in which B-Raf is wild type, this inhibitor can stimulate signaling, possibly by activating C-Raf. (A, from H. Davies et al., *Nature* 417:949–954, 2002. B, from G. Hatzivassiliou et al.,

Nature 464:431–435, 2010. Both with permission from Nature. C, courtesy of M.B. Yaffe.)

In 2011, the drug vemurafenib (previously called PLX4032), which targets specifically the V600E mutant B-Raf protein, received approval for use in metastatic melanomas in Europe, followed soon thereafter by approval in the United States. It was the first time that these aggressive, late-stage tumors could be treated with significant clinical responses. Thus, over a 6-month trial period, vemurafenib produced a 74% increase in progression-free survival (PFS) and a 20% reduction in overall mortality relative to the standard of care at the time, an alkylating agent named dacarbazine. Stated differently, vemurafenib increased overall PFS of these patients by ~4 months. These numbers indicate that vemurafenib offers patients with V600E metastatic melanomas an extension of life span but only rarely a cure. Sooner or later, their tumors develop strategies for evading this drug and thereby acquire the ability to erupt again, although many of these relapsed tumors can now be treated effectively with checkpoint blockade immunotherapy, as discussed in Chapter 16.

Curiously, a significant percentage of vemurafenib-treated patients develop cutaneous squamous cell carcinomas, providing a clear indication that, paradoxically, this drug *stimulates* the outgrowth of previously latent, subclinical tumors. Indeed, in patients whose tumors carried mutations other than the V600E alteration, vemurafenib actually *favored* tumor growth, indicating the critical importance of sequence analysis of tumors prior to use of this drug.

One possible explanation for this apparently paradoxical biology is that ATP-competitive Raf inhibitors inhibit mutant B-Raf activity, but unexpectedly activate wild-type B-Raf signaling. Here, drug interaction with the ATP-binding pocket of one B-Raf protein within a B-Raf dimer leads to the activation of the other component of the dimer. This activation is dependent upon Ras activity and can result in elevated MEK/ERK activation in non-tumor cells (including, possibly, subclinical squamous cell carcinomas). The relevance of this unexpected biology is worth noting in the context of the therapeutic index. Because vemurafenib (and other Raf inhibitors) activates the Ras/MAPK pathway in normal cells, rather than inhibiting it, it is possible to apply very high doses of drug to treat the tumor. This therapeutic index also allows co-treatment with a MEK inhibitor to increase the potency of vemurafinib in the tumor without the usual toxicity of a MEK inhibitor in normal tissue.

Another explanation for this phenomenon relates to the propensity of deregulated Ras expression to promote the process of cellular senescence, as described in Section 9.11. Studies of transplanted melanomas in mice showed that tumors that acquired the ability to grow in the presence of vemurafenib actually developed a dependence on continued drug treatment. Here, resistance to vemurafenib treatment resulted from hyperactivation of Ras signaling and cessation of vemurafenib treatment, by reactivating B-Raf, led to elevation of already high levels of Ras signaling to a level at which Ras-induced senescence occurred. Conversely, in the context of squamous cell carcinomas, it is possible that vemurafenib treatment decreases senescence induction in pre-neoplastic lesions, allowing skin tumors to progress. The ability to engage a senescence response by halting vemurafenib treatment has promoted the idea that intermittent drug holidays, periods in which patients are not administered therapy, may promote better overall tumor control. This result highlights the idea, supported largely by empirical data, that the timing and scheduling of drug treatments can decidedly affect the therapeutic response.

The development of anti-tumor immunotherapies (as described in Chapter 16) has profoundly altered the treatment of melanoma. Still, vemurafenib has the prospect of becoming part of a multi-drug treatment protocol that one day will stop the previously unstoppable metastatic melanomas in their tracks. Indeed, vemurafenib is now used in combination with Mek inhibitors to treat B-Raf mutant melanoma. Additionally, an increasing number of tumors beyond melanoma have been shown to rely on signaling pathways that require B-Raf, and B-Raf mutation and activation can promote tumor cell resistance to targeted therapies, including EGF-R inhibitors in lung cancer. Thus, although not as effective as Gleevec before it, this drug confers significant benefit in melanoma patients and provides support for the goal of treating multiple primary and drug-resistant cancers with rationally developed drugs.

17.17 Synopsis and prospects: challenges and opportunities on the road ahead

“When is cancer going to be cured?” This is the simple and reasonable question posed most often to cancer researchers by those who are not directly involved in this area of biomedical research. In their minds are the histories of other public health measures. Infectious diseases, such as polio and smallpox, can be prevented, and bacterial infections are, almost invariably, cured. Heart disease is, in the eyes of many, well on its way to being prevented. Why should cancer be any different?

The information in this book provides some insights into the answers to these questions. As much as we have invoked unifying concepts to portray cancer as a single disease, the reality—at least in the eyes of clinical oncologists—is far different. Cancer is really a collection of more than 200 diseases, each affecting a distinct cell or tissue type in the body.

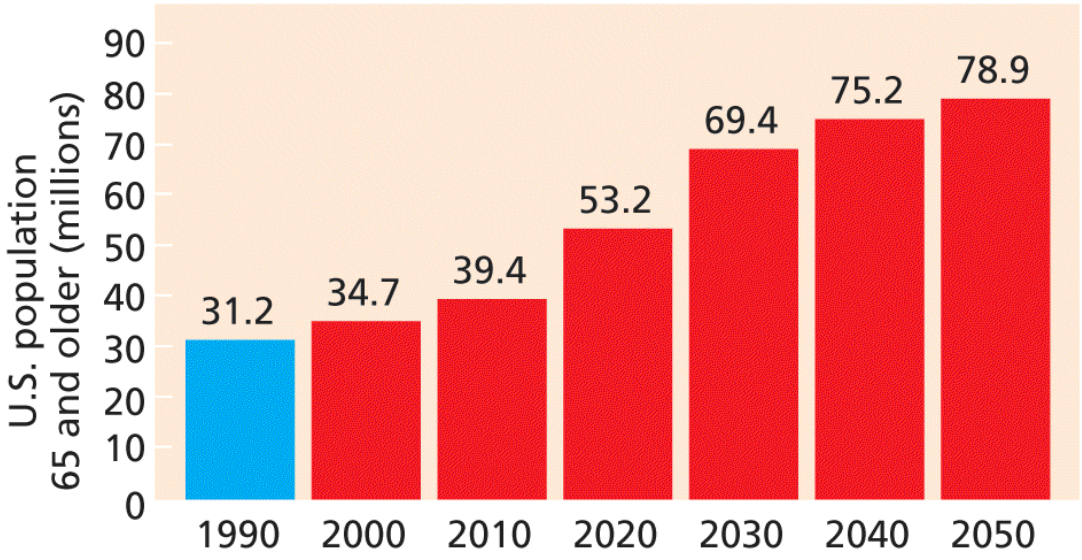
Pathological analyses have led us to embrace this number, or one a bit larger. (For example, there are at least eight distinct histopathological categories of breast cancer.) However, even the expanded number, large as it may be, represents an illusion: the current use of molecular diagnostics, specifically gene expression arrays, is leading to an explosion of subcategories, so that several hundred distinct neoplastic disease entities are likely to be recognized, each following its own, reasonably predictable clinical course and exhibiting its own responsiveness to specific forms of therapy. With the passage of time, cancer diagnoses will increasingly be made using bioinformatics rather than the trained eyes of a pathologist.

So the initial response to questions about “the cure” is that there won’t be a single major breakthrough that will cure all cancers—a decisive battlefield victory—simply because cancer is not a single disease. Instead, there will be many small skirmishes that will steadily reduce the overall death rates from various types of cancer. And because certain molecular defects and pathological processes (for example, immune evasion) are shared by multiple human cancers, there will be occasions when therapeutic advances on a number of fronts will be made concomitantly.

Before we speculate on the future of cancer therapy, it is worthwhile to step back and assess the scope of the challenge: (1) How large is the problem of cancer and, in the

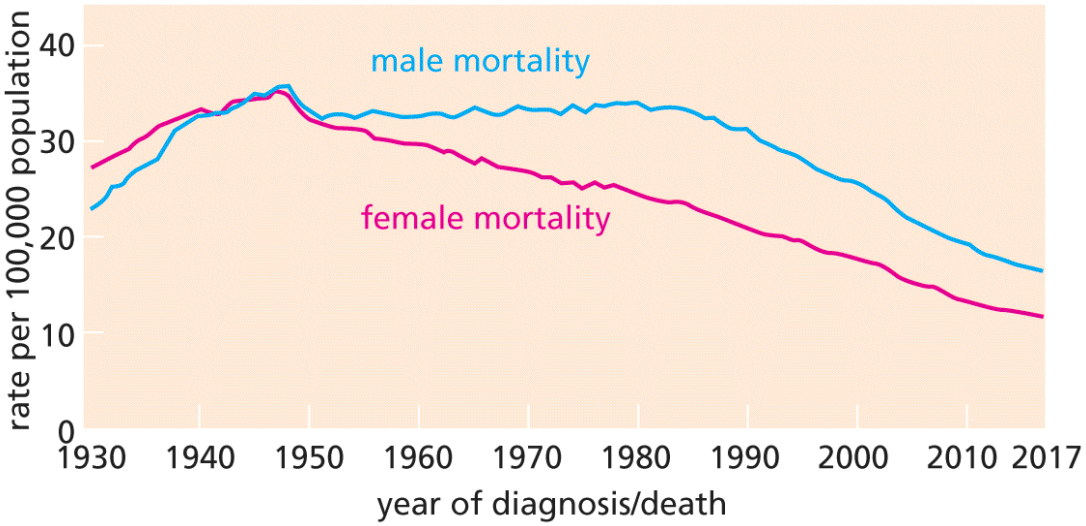
future, how desperate will the need be to cure various types of neoplastic disease? (2) How well are we doing now in curing the major solid tumors?

Epidemiology and demographics provide some answers to the first question. They yield sobering assessments of the road ahead. The statistics illustrated in Figure 11.1 and cited in **Figure 17.44** demonstrate that cancer is largely a disease of the elderly, whose numbers are growing rapidly and will continue to do so, generating progressive increases in the numbers of cases of cancer-related deaths (mortality) over the coming decades.



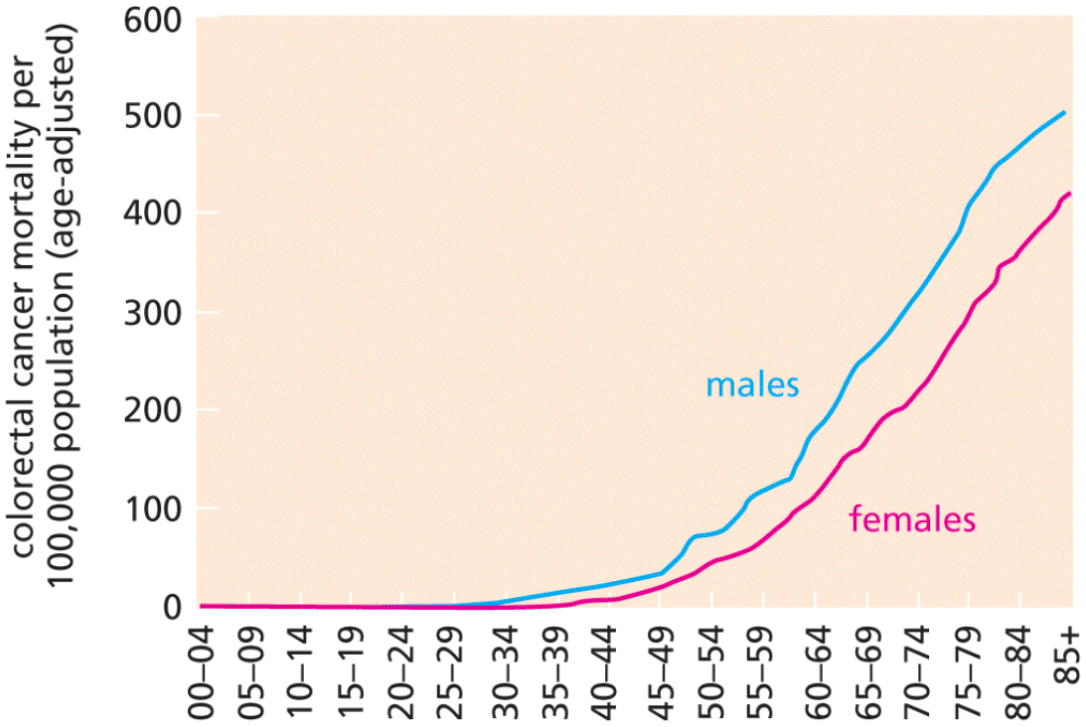
A bar graph shows the number of the U.S. population that is 65 and older for different years. In 1990, there were 31.2 million. In 2000, there were 34.7 million. In 2010, there were 39.4 million. In 2020, there were 53.2 million. In 2030, there will be 69.4 million. In 2040, there will be 75.2 million. In 2050, there will be 78.9 million.

(A)



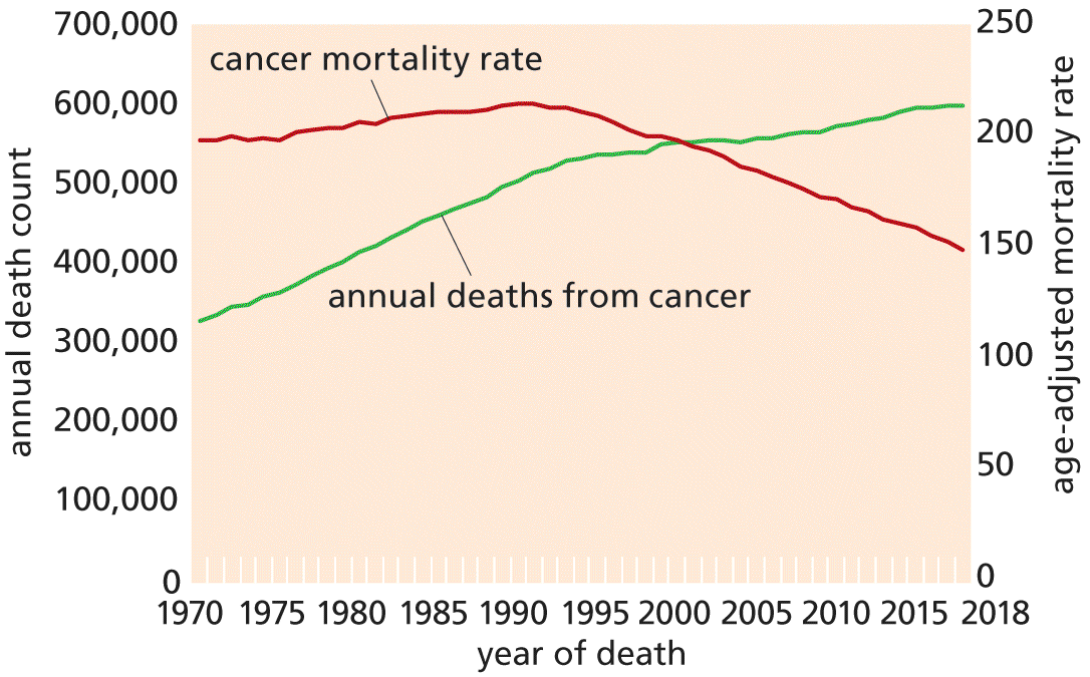
A line graph shows the female and male mortality rates relative to the year of diagnosis or death from 1930 to 2017. Both follow the same trajectory with a peak mortality rate at the year 1950. After 1950, female mortality rate decreases steadily to around 15 per 100,000 population in 2017. Male mortality plateaus around 30 per 100,000, until 1990, when it starts to decrease. By 2017, it is around 20 per 100,000.

(B)



A line graph of colorectal cancer mortality for different genders and age groups. For both males and females, mortality per 100,000 people is 0 until around age 29. After that, the mortality increases somewhat exponentially. At age 85 plus, the mortality per 100,000 people reaches about 510 for males and 425 for females.

(C)



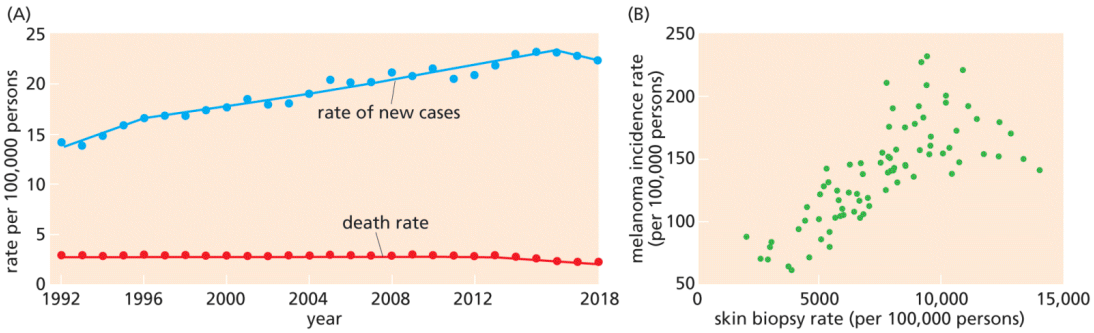
A line graph shows the cancer mortality rate and annual deaths from cancer from 1970 to 2018. The annual deaths from cancer increases from just over 300,000 in 1970 to around 600,000 in 2018. The age adjusted cancer mortality rate stays around 200 from 1970 to 1990 and then decreases to 150 by 2018.

(D)

Figure 17.44 The demographics and epidemiology of cancer (A) Because of dramatic decreases in midlife mortality, populations in industrialized countries are aging rapidly. In the United States, the number of individuals over 65 years of age has increased elevenfold since 1900, while the number of those under 65 has increased by a factor of 3. Comparable increases in the aged population are likely to occur worldwide over the next generation. (B) The age-adjusted death rate from colorectal cancer has changed only slightly over the past several decades. Other major cancers show similar curves. (C) Like many other diseases, cancer is uncommon during early and midlife and then increases rapidly. Shown here is the age-dependent death rate of colorectal cancer. (D) Because (1) the number of

elderly individuals has increased steadily over the past century and will continue to do so (see panel A), (2) cancer is a disease of the elderly (panel C), and (3) the age-adjusted death rate of most cancers has been declining only slowly (as suggested in panel B), the absolute number of annual deaths from cancer has increased dramatically over the past three-quarters of a century in the United States (red line) despite an overall decrease in age-adjusted mortality (blue line, a death rate that controls for the effects of differences in population age distributions). (The number of individuals afflicted with Alzheimer's disease has increased in parallel for the same reasons.) Because these trends are likely to continue, the burden of cancer cases in industrialized societies will continue to climb for many decades, albeit at a slower rate than before 1995. (A, courtesy of D. Singer and R. Hodes, from U.S. Bureau of the Census, Projections of 1996. B, from R. Siegel et al., *CA Cancer J Clin*. 70(3):145–164, 2020. With permission from John Wiley & Sons. C and D, from Natl. Cancer Inst, DCCPS, Surveillance Res. Program, May 2020 and the American Cancer Society.)

Equally important, we still have only very imperfect ways of measuring incidence—how often the disease strikes. This greatly complicates assessments of the effectiveness of current therapies and future needs for therapy. As indicated in **Figure 17.45**, perceptions of the incidence of certain types of neoplastic disease are strongly influenced by diagnostic practices.



Two graphs describe melanoma incidence and mortality. Part A. A line graph shows the death rate and rate of new cases of melanoma from 1992 to 2018. The death rate remains around 3 per 100,000 people across all years. However, the rate of new cases starts near 15 per 100,000 people and increases to a peak of 24 per 100,000 people around 2016. Part B. A scatterplot shows the melanoma incidence rate relative to the skin biopsy rate per 100,000 people. In general, the incidence rate increases as the biopsy rate increases. For instance, a biopsy rate of 5000 per 100,000 people is associated with an incidence rate of 100 per 100,000 people. A biopsy rate of 10,000 per 100,000 people is associated with an incidence rate of 150 per 100,000 people.

Figure 17.45 Melanoma incidence and mortality Melanoma incidence in the United States has increased by a factor of 6 over the past half century, raising the question whether this trend has created a comparable increase in the number of cases that truly require aggressive clinical treatment. (A) The age-adjusted breakdown of melanoma incidence, collected from 13 locations within the United States, indicates a dramatic increase over the past three decades in the overall incidence rate of disease (*blue curve*). The age-adjusted mortality rate (*red curve*) has been relatively constant during these years. These data raise the question: Has the real incidence of life-threatening disease been relatively constant over this period and has the registered incidence of this disease increased from changes in screening practices, revealing increasing numbers of non-life-threatening early-stage disease? (B) If melanoma incidence rates are plotted against the rates of screening of people aged 65 or over for melanoma in nine areas of the United States, as registered during several time periods between 2002 and 2009, the resulting scatter plot reveals a close correlation between the two. This provides a strong indication that the incidence of the disease is strongly influenced by diagnostic practices. It is therefore possible that (1) the true incidence of life-threatening melanomas (panel A) has not changed significantly over the past two decades; or (2) the true incidence of these tumors has increased, but intensification of screening has held the mortality rate at levels observed two decades ago by allowing the removal of early-stage tumors before they progress to become invasive and metastatic. (A, from https://seer.cancer.gov/statfacts/html/melan.html and H. G. Welch et al., *BMJ.* 331:481–484, 2005; B, from M. A. Weinstock et al, *Br. J. Dermatol*. 176: 949–954, 2016. With permission from John Wiley & Sons.)

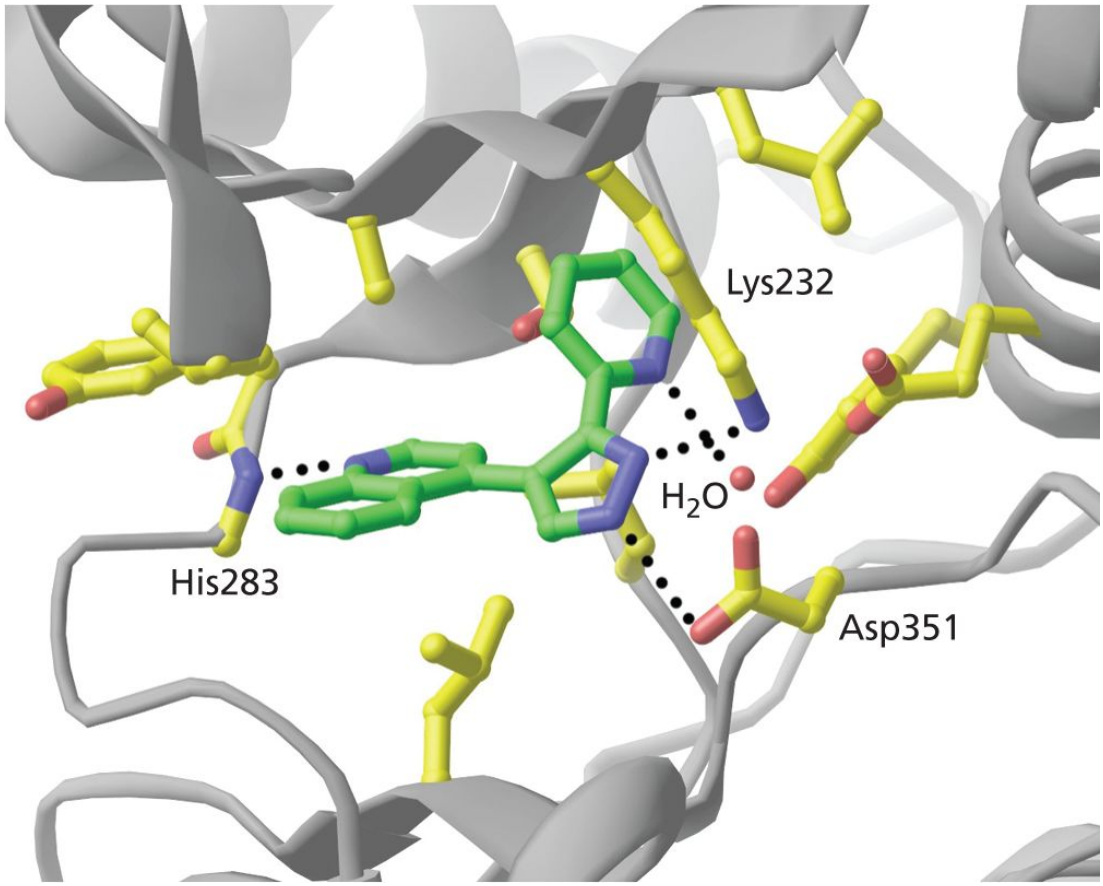
For many types of cancer, the more one looks, the more one finds. Statistics like those in Figure 17.45 suggest that, in the past, many cancers remained undiagnosed and asymptomatic for the lifetimes of those who carried them and that tumors of this class are contributing the lion's share to the perceived increases in disease incidence, notably of common tumors, such as those arising in the breast and prostate. (The major exceptions here are the cancers related to tobacco use, whose increased incidence in certain populations is real and beyond dispute because the incidence rates are closely paralleled by the rates of mortality.) Such statistics indicate that for certain common tumors—prostate and breast cancer being prominent examples—we have only a poor appreciation of the number of tumors that truly require treatment (see **Supplementary Sidebar 17.2**). Given these numbers, the current practice in the West of aggressively treating all individuals diagnosed with cancer (whether or not they truly require such treatment) will soon exceed the ability of national economies to support such care.

Data like those in Figure 17.45 also undermine the notion, deeply entrenched in the thinking of many cancer biologists and clinical oncologists, that all benign growths are in danger of becoming, sooner or later, highly malignant ones (see Chapter 11). Cancer

epidemiology now makes us confront the alternative possibility: many kinds of early-stage tumors are unlikely to progress to high-grade malignancy during an average human life span, and the long-term side effects of aggressive treatment may often be more serious than the statistical likelihood of dying from these tumors. Unfortunately, we are only beginning to learn how to segregate those tumors that are truly deserving of aggressive treatment from those that are not (see, for example, Figure 17.4).

As to the second question, which deals with the effectiveness of current cancer therapies, our perceptions have been strongly influenced by the fact that people are living longer with their cancers. This increase in longevity would seem to provide some reassurance that real progress is being made. However, some of these perceived improvements in therapy may, once again, be artifacts of increased screening and more sensitive detection techniques that increasingly uncover tumors relatively early in their development, giving the patient additional years of survival before tumor progression advances through its natural course, whether or not treatments are applied. This logic forces the conclusion that the efficacy of therapies can be accurately gauged only by well-controlled experiments: comparisons of several patient populations that are afflicted by the same malignancy and exposed in parallel to different agents or treatment protocols. Such side-by-side comparisons have, until recently, yielded only incremental gains in treating most solid tumors (see, for example, Figure 17.25), but this is beginning to change as new drugs and immune therapies are introduced into the clinic. Indeed, the age-adjusted mortality from breast cancer in Western countries has decreased by 40% in certain cohorts of women, and most of this decrease is likely attributable to aggressive clinical intervention.

The major hope at present is that agents such as Gleevec, erlotinib, vemurafenib, and rituximab are the forerunners of dozens and eventually hundreds of targeted, highly efficacious drugs. Computer-driven procedures, including high-throughput screening (HTS), automated determinations of the stereochemical structures of target molecules, and computer-aided design of drug molecules (**Figure 17.46**), are proving useful in this endeavor. Without such automated procedures, the current costs of developing novel anti-cancer drugs will soon become economically unsustainable, and the development of agents for less common subtypes of common cancers will never be realized.



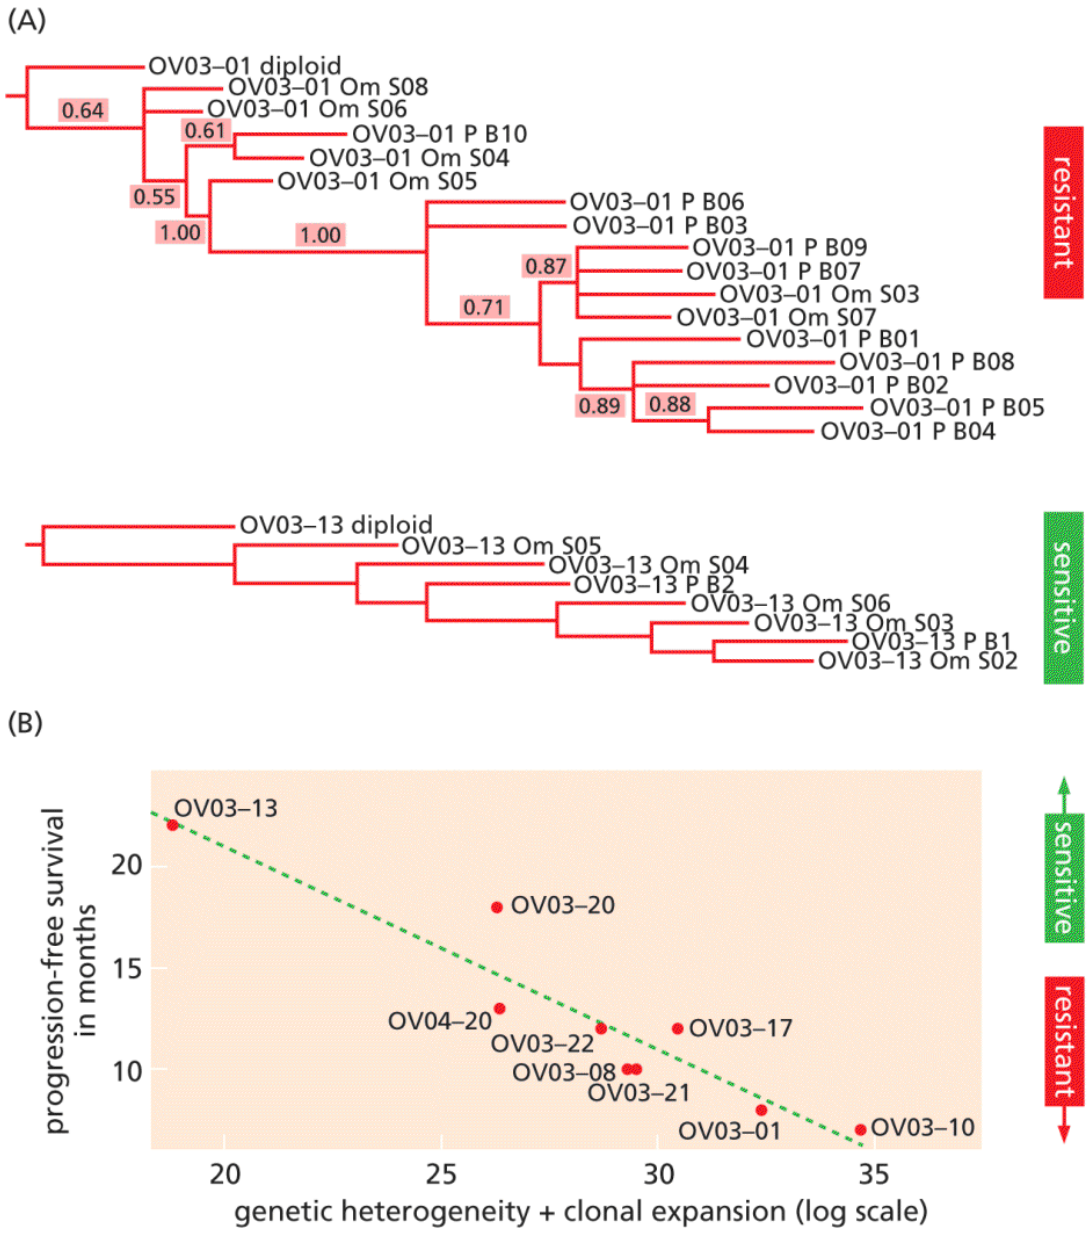
A diagram shows a drug molecule interacting with the Histidine 283, Lysine 232, and Asparagine 351 of a T G H beta type 1 receptor kinase.

Figure 17.46 Virtual screening—designing drugs using the desktop computer High-throughput drug screening using various cancer cells as targets has yielded a large number of highly attractive drug candidates, many of which have advanced into clinical trials. In the future, however, much of this screening, which is very expensive, may be obviated by the development of powerful algorithms that enable pharmacologists to design drugs using the known stereochemical structures of target proteins. The development of the drug illustrated here began with a compound that showed very weak affinity (IC_{50} of 30 μM) for the ATP-binding site of the TGF-β type I receptor kinase. Researchers then queried a database of 200,000 known compounds for ones that shared some chemical features with the starting compound and conformed to the constraints imposed by the known structure of the ATP-binding site. This yielded the structures of 87 chemical species that satisfied these criteria and were then screened using conventional biochemical techniques. One of these, named HTS466284, is shown here ensconced in the ATP-binding site of the TGF-β type I receptor kinase; it exhibits an IC_{50} of 27 nM and thus functions as a potent inhibitor of TGF-β signaling.

Significantly, another research group, working independently, arrived at the identical inhibitor molecule using conventional high-throughput screening. Hydrogen bonds are indicated by dotted lines. (From J. Singh et al., *Bioorg. Med. Chem. Lett.* 13:4355–4359, 2003. With permission from Elsevier.)

Ultimately, the biggest challenge of drug development now and in the future is to demonstrate long-term efficacy: Does a drug being tested have significant effects on extending the life expectancy of cancer patients, doing so with acceptable levels of side-effect toxicities? And do we dare to hope that it can achieve durable responses, including cures?

As mentioned repeatedly here, rapidly evolving populations of cancer cells develop drug-evading mechanisms that protect them from many types of therapeutic attack. Indeed, recent evidence demonstrates directly that tumors that undergo more genetic diversification and thus evolution are likely to be more resistant to therapy (**Figure 17.47**). Some populations of cancer cells may develop drug evasion mechanisms by increasing their anti-apoptotic defenses (see Table 17.5). Yet others may lose checkpoint controls that previously made them sensitive to certain types of drug treatment, or evade the effects of administered drugs either by altering drug metabolism or enhancing drug efflux. Tumors whose cells were previously being killed through antibody-mediated attack may simply down-regulate expression of the telltale antigen. At present, it remains unclear whether we will, one day, be able to devise treatment strategies that anticipate the plasticity and evasiveness of cancer cells, allowing us to develop definitive cures of malignancies that have long been incurable.



A two part figure demonstrates the genetic diversification of tumors and their resistance to therapy. Part A. Phylogenetic trees for a tumor population that was resistant to treatment and one that was sensitive to treatment. The tree of the resistant tumor has many more branches and many more cell subpopulations than the tree of the sensitive tumor. Part B. A scatterplot of genetic traits of 9 ovarian tumors. On the x axis is genetic heterogeneity and clonal expression on the log scale. On the y axis is progression-free survival in months from 5 to 25. A dashed linear line with a negative slope runs from around a genetic heterogeneity of 20 and 20 months to around 35 and 5 months. The points representing different tumors generally follow this line.

Figure 17.47 Genetic diversification and resistance to therapy A widely embraced notion is that tumors develop resistance to therapy through a process of genetic diversification followed by the selection and outgrowth of more therapy-resistant subpopulations of cells—a model formally akin to Darwinian evolution. This notion has rarely been tested experimentally in a clinical setting. As shown here, the ovarian tumors of individual patients were sampled successively during the course of their treatment, and the interrelatedness and thus genetic diversification of subpopulations within their tumors were gauged using genome sequence analyses and a bioinformatics algorithm. (A) The genetic relatedness of the subclones within two patients is indicated here. As is apparent, the tumor subpopulations within a patient whose ovarian carcinoma became resistant to therapy (*above*) exhibit extensive diversification, with multiple branch points illustrating the relationships among cell subpopulations within her tumor. Conversely, a patient whose tumor was sensitive to treatment (*below*) showed minimal branching and thus minimal genetic diversification of cancer cell populations. (B) The genetic behavior of nine ovarian tumors and the clinical progression of the patients carrying them are plotted here. As is apparent, a metric of intra-tumor genetic heterogeneity within individual tumors (*abscissa*) is correlated inversely with the extent of progression-free survival (*ordinate*). (Courtesy of R. Schwarz, J.D. Brenton, and F. Markowetz.)

These evasive maneuvers of cancer cells underlie the growing conviction of cancer researchers that most monotherapies are unlikely to yield curative treatments because they are destined to select for the outgrowth of variant cells within tumors that happen to have developed resistance to the single agent being applied. Such logic dictates that truly successful clinical outcomes and durable clinical responses will depend in the future on the development of multi-drug therapies and on the low probability that a clinically detectable tumor will harbor individual cancer cells that exhibit concomitant resistance to all of the cytotoxic agents dispatched to kill them.

This development of therapeutic resistance occurs sooner or later following long-term treatment of a variety of common human cancers. Included among these are high-grade tumors of the lung, breast, prostate, pancreas, ovary, and liver. Such acquired resistance represents the secondary resistance described earlier and indicates the grim scenario confronting medical oncologists at present, because it means that most therapeutic protocols (including those involving multi-drug therapy) will provide only a temporary respite from disease progression. As a consequence, the medical oncologist needs to respond, time after time, to the latest clinical relapse in a patient by devising a new protocol that responds to the most recent evasive maneuver developed by the patient’s tumor.

The replacement of one therapeutic protocol that has failed a patient with another requires some understanding of the resistance mechanisms that have provoked clinical relapse and allowed therapy-resistant tumors to grow out. Indeed, in certain cancers, like EGF-R- or ALK-driven lung cancer or Bcr-Abl–driven leukemia, we have a very good understanding of the multiple alternative pathways toward resistance that are sought out by the neoplastic cells under treatment, including treatments involving targeted agents. Moreover, we have myriad new therapies that target the acquired resistant states.

Still, fundamental questions remain regarding how we should treat patients exposed to front-line therapies. For example, can we predict which pathway of resistance will eventually emerge in a given tumor? Can we direct tumors to evolve toward specific resistance states that we are better able to treat? And can we preempt the development of resistance by adding a second-line therapy drug that targets the emergent vulnerabilities of therapy-resistant tumor cells? Additionally, in an ideal world, each of this succession of treatment protocols would provoke tolerable levels of side-effect toxicities, and the sequence of treatments would allow the cancer patient to live in a relatively symptom-free state, surviving in many cases to the end of what would be a normally expected life span. We are still very far from reaching this goal.

Clearly, cell-intrinsic (as opposed to microenvironment-mediated) drug resistance derives from the instability of cancer cell genotypes and phenotypes that allow the emergence of therapy-resistant variant cell clones, as detailed in Chapter 12. The evidence presented in Figure 17.47 provides possibly the first direct demonstration that genetic plasticity plays a central role in generating secondary resistance. In truth, however, we still do not understand how much of this secondary resistance derives from genetic instability and how much can be traced to shifts in the cell-heritable epigenetic programs (see Section 1.8) of these cells.

Here we also confront the fact that there are still no clear and logical strategies for designing multi-drug therapies, beyond the strategy that has been in place for half a century: choose combinations of drugs having cytotoxic mechanisms of action that are distinct from one another, doing so with the hope that they will act synergistically to reduce the burden of cancer cells in a patient’s body below the threshold level at which the clinical resurgence of the disease becomes likely.

The lack of clear therapeutic strategies regarding the construction of multi-drug regimens also suggests a related question: What if the real powers of a drug under development are only realizable when it is used in combination with several others? In theory, many anti-cancer agents should fall into this category. If true, it suggests that many truly useful drug candidates have been discarded in the past, having failed tests in monotherapy trials, and that many others will suffer this fate in the future, simply because their true utility as components of multi-drug treatment protocols will never

be tested. Here again, one hopes that our increasing understanding of the subcellular signaling circuitry will ameliorate this situation (**Sidebar 17.16**).

Sidebar 17.16 Legal and financial disincentives decrease the likelihood of drugs being tested in combination

At present, the biological difficulties of testing candidate drugs in combination with others are compounded by economic forces that often create disincentives for pharmaceutical companies to test their own proprietary drugs in combination with those produced by their competitors. Patent regulations have also discouraged certain uses of patented compounds by firms that are in direct competition with the patent holders.

In the past, the difficulties of organizing early multi-drug clinical trials were further compounded in the United States by the Food and Drug Administration's (FDA's) insistence that the clinical efficacy of drug candidates be demonstrated first as monotherapies. But this practice has begun to change, albeit slowly. For example, Erbitux, the anti-EGF-receptor monoclonal antibody (see Sidebar 15.5), was initially approved for use together with irinotecan because the two used in concert yielded far better responses than did irinotecan on its own. (Irinotecan is a more traditional cytotoxic agent that functions as a topoisomerase I inhibitor; see Table 17.2.)

The existence of tumor stem cells (see Section 11.6) creates another major challenge for anti-cancer drug development. Recall that the self-renewing cancer stem cells (CSCs) can seed new tumors, whereas their far more numerous transit-amplifying progeny, with limited self-renewal capacity, cannot. Such a hierarchical organization was demonstrated initially in leukemias, breast carcinomas, and brain tumors, but it probably exists in most tumors and holds important implications for the development of anti-cancer drugs. Traditionally, clinical validation of the therapeutic efficacy of these drugs has depended on demonstrations of their ability to halt further tumor growth or decrease tumor size. Many anti-tumor agents in clinical trials may shrink tumor masses by eliminating populations of transit-amplifying and more differentiated neoplastic cells, which together constitute the great bulk of the tumors' cellularity. However, if such drugs leave the minority populations of self-renewing CSCs untouched (see Figure 17.35A), the tumor has a high probability of regrowing, leading sooner or later to clinical relapse. Indeed, as mentioned, there is clear evidence that CSCs are more resistant to a variety of modes of current anti-cancer therapy (see Sidebar 17.13).

Such evidence suggests that durable remissions and cures can only derive from therapies that strike both the majority of non-CSCs in tumors and, importantly, those

that lie at the heart of the tumor—the self-renewing CSCs. Currently, assays for the presence of these cells in most tumor types are poorly developed. Hence, drug development efforts are hobbled in part because researchers lack key analytical tools that are essential for developing truly efficacious therapies.

But there is another problem that has only recently emerged: the non-CSCs within a tumor, more specifically the transit-amplifying/progenitor cells (see Figure 11.20C), are able in some tumors, and quite possibly in most tumors, to dedifferentiate and thereby form new CSCs (see Figure 17.35C). If validated as a general phenomenon, this tumor cell plasticity adds emphasis to the necessity of eliminating both the existing CSCs within tumors as well as their more differentiated progeny, which may wait in the wings, always poised to regenerate new CSCs.

A major, still-unsolved problem concerns the biological models that are used in pre-clinical drug development. Some xenograft models of human cancer are useful in predicting the behavior of tumors encountered in the oncology clinic, but most are not (see Sidebar 13.13). Similarly, genetically engineered mouse models of human cancer have been limited in their ability to predict clinical responses. However, we now have an expanding array of tumor cell lines, organoid models, primary human patient-derived xenograft (PDX) models, and "humanized" mouse tumors, as well as gene-editing technologies that permit the re-creation of complex tumor genomes. The use of these systems to create predictive pre-clinical models of human cancer will surely reduce the expense of drug development and, quite possibly, even obviate certain early-phase clinical trials.

The non-neoplastic stromal cell types within a tumor may be major determinants of responsiveness to most drug therapies, yet their proportions and respective contributions are not recognized in the design of most pre-clinical models of human cancer. In Chapter 13, we learned, for example, that the most radiosensitive cells in some tumors are likely to be the endothelial cells forming their neovasculature (see **Supplementary Sidebar 13.10**). By the same token, it seems increasingly likely that many widely used anti-cancer chemotherapeutics have strong effects on the tumor-associated endothelial cells that were never suspected in the past. In fact, some researchers are redesigning chemotherapeutic treatment protocols in order to optimize their toxic effects on the tumor-associated neovasculature. Recognition of these two classes of tumor-associated cells—cancer stem cells and stromal cells—as critically important biological targets of chemotherapy will surely change the entire landscape of the drug development field. Moreover, the concept of "stroma" will surely be expanded to include the microenvironments of tumor cells throughout the body as we learn that certain sites of metastatic dissemination offer particularly hospitable homes for cancer cells, protecting them from the toxic effects of various therapies.

The ultimate test of many candidate anti-cancer drugs comes when they are first tested in substantial numbers of cancer patients. Here, the drug developer is often confronted by the dilemma of not knowing which types of tumors are likely to respond. Should a candidate drug be tested on patients suffering from pancreatic carcinomas or neuroblastomas? The molecular lesions discovered in these and other types of cancer cells would seem to be highly useful indicators for informing this decision. But quite often, tumors respond for reasons that cannot be predicted by the mutant genes and deregulated signaling pathways known to be present in these growths, and so the choices of patients recruited into clinical trials are arbitrary and sub-optimal. Once again, we can only hope that our increasing insights into the molecular etiologies of various cancers will provide truly useful guidelines for oncologists to follow.

Independent of the challenges of cancer drug development and testing are the more transcendent problems created by the complex biology of human cancers: Will different types of drugs need to be developed for different classes of cancers or will a small number of treatments find wide applicability? Will different tumors within a given class (for example, colon carcinomas) require distinct, tailor-made treatments based on their particular genotypes and phenotypes? And will we one day be able to provide “personalized molecular medicine” at an affordable cost, in which the detailed characteristics of each patient’s tumor genome, transcriptome, and proteome inform the design of a customized therapy?

Will anti-neoplastic drugs ever be developed that have lethal effects on malignant growths while having minimal side effects on normal tissues? And should drug designers undertake to develop anti-cancer drugs that keep tumors under control rather than attempting to wipe them out? The goal of curing many kinds of tumors, cited above, may well be an unreachable one, and for these tumors, reducing cancer to a chronic but bearable disease may be a more realizable goal. (Such is the thinking of researchers developing new types of anti-HIV treatment protocols, some of which have achieved this goal.)

A recent census of genes mutated in human cancer cell genomes describes 576 distinct genes—more than 2% of the genes present in the human genome. Of these, 533 become involved in cancer largely through somatic mutation, while the remaining 43 are exclusively inherited as germ-line determinants of cancer susceptibility. This list—generated in significant part from the results of cancer genome sequencing—will likely grow somewhat in the future. The list of somatically altered genes will be increased by inclusion of myriad tumor suppressor genes that are shut down by promoter methylation; recall that promoter methylation is as effective as genetic mutation in eliminating genes and proteins from the regulatory circuitry of cells. At the same time, the census of germ-line determinants of cancer will expand as alleles (and thus genes) having less penetrant effects on cancer susceptibility are uncovered.

This census suggests many druggable targets for researchers. At the same time, it represents bewildering complexity. Some of these genes are mutated only in rare cancers, and the costs of developing therapeutic drugs directed against their protein products are unlikely to ever be recouped through drug sales. Most of the encoded mutant proteins contribute in still-obscure ways to the neoplastic growth of various types of human cancer cells. How will we ever ascribe key roles to each of the more than 570 mutant genes that are already known or suspected to be involved in the pathogenesis of many cancers? [Of relevance here is that only a limited portion of the **human kinome** (see **Supplementary Sidebar 17.7**) has been extensively explored by laboratory researchers and pharmaceutical chemists. A 2009 survey indicated that half of the kinome (a total of ~522 protein kinases) had been described by 20 or fewer research publications, in contrast to 10 kinases (all discussed in some detail in this book) that had been the topics of 5000 or more reports. Additionally, less than 10% of the kinome has been successfully targeted in the form of FDA-approved therapies. Many of the under-studied, potentially druggable enzymes are likely to participate in tumor pathogenesis, even when present in wild-type configuration within cancer cells. Hence, a large array of potentially targetable kinases has yet to be intensively explored.]

Many cancer researchers would like to understand the entirety of a biological system, such as a living cancer cell, rather than its individual functional components. In their eyes, reductionist biology, which focuses on the individual, isolatable components of complex systems, has had its day, and the time has come for the vast amounts of information known about these components to be integrated into complex interacting *systems* whose behavior can be predicted by bioinformatics.

Successes in these efforts, involving the new discipline of "systems biology," will surely benefit cancer research. Imagine a day when the biological responses of various human cells, normal and malignant, can be predicted by mathematical models of these cells and their internal control circuits. Such advances will render many current practices in experimental biology, including many steps of drug development, unnecessary. If this ever becomes possible, drug development will be more a matter of dry bioinformatics than wet biology at the laboratory bench.

But for the moment, most of this remains a pipe dream, still far in the future. For now, at least, we need to wrestle with the grim realities of drug development, the inadequate animal models, our ignorance of the behavior of cellular regulatory circuitry, and the confounding biological complexities of human cancer. And most importantly, we must never give up. If our ancestors had, we would still be living in the Stone Age.

kinome
: The complete repertoire of kinases encoded by a genome, such as the human genome.

OceanofPDF.com

Key concepts

- The science of molecular oncology has revealed hundreds of proteins whose malfunction contributes to the formation and maintenance of tumors. Many of these proteins exhibit molecular properties that make them attractive targets for novel anti-cancer therapeutic agents, such as monoclonal antibodies or low–molecular-weight drugs.
- Proteins that are attractive targets for attack by antibodies are invariably located at the cell surface or in the extracellular space.
- Most proteins that are attractive targets for attack by low–molecular-weight compounds are enzymes that possess druggable catalytic clefts.
- Recent advances have expanded the range of druggable targets to include certain protein–protein interactions and protein conformational states that can also be inhibited by low–molecular-weight drugs.
- The proteins that are most suitable as targets are those whose inactivation is predicted to make tumor cells cease proliferating, to promote cell differentiation, or to lead to their death by apoptosis.
- The most successful targeted anti-cancer drugs developed to date have been those that interfere with the functioning of various growth- and survival-promoting kinases, specifically, receptor-associated tyrosine kinases.
- Successful drugs must have a high therapeutic index, appropriate pharmacokinetics and pharmacodynamics, and minimal side effects on major organ systems.
- Studies of drugs in Phase I, II, and III clinical trials are essential because pre-clinical studies of drugs' efficacy and tolerability are poorly predictive of the drugs' behavior in humans.
- Clinical use of certain drugs under development may be indicated by the known behavior of targeted proteins in cancer cells (as in the case of Gleevec) or by empirical tests of how various types of human tumors respond to treatment (as with Velcade).
- Stratification of outwardly similar tumors into narrow subclasses greatly helps researchers and clinicians to match drugs to the specific tumor cell types they can most effectively treat.

- The greatest benefit of certain drugs, such as Gleevec, may eventually prove to derive from a broad target specificity that allows them to target multiple pathways in tumor cells and adjacent stromal cells in a wide range of cancers.
- The treatment of tumors with targeted therapies is almost universally accompanied by the development of drug resistance, and so treatment strategies that target the resistant state are critical for durable responses.

Thought questions

1. What are the therapeutic advantages and disadvantages of using a drug that affects a broad range of molecular targets?
2. Given the large and heterogeneous collection of signaling molecules that have been portrayed in this book as playing key roles in the pathogenesis of various cancers, which classes of molecules do you think might become the targets for the development of a new range of anti-cancer therapeutics besides the much-studied kinases?
3. How might tumors that were initiated by the formation of a certain oncogene become independent of this oncogene later in tumor progression?
4. What strategies might you implement to preempt the development of tumor drug resistance or target the drug resistant state?
5. Having concluded that natural products represent a rich resource of potential anti-cancer drugs, what obstacles might limit the search for and testing of such drugs?
6. What obstacles stand in the way of developing drugs for tumors that represent only a very small proportion of the total cancer burden in a population?
7. In the oncology clinic of the future, what types of information might be included in the assembly of anti-cancer therapies that are tailor-made specifically to respond to an individual patient's tumor?
8. Given the new tools available (including gene editing technology) for cancer cell target identification, what criteria should be used to nominate potential drug targets for clinical development?
9. What strategies would you pursue to develop pre-clinical models of human tumors that are highly useful in predicting patient responses to candidate drugs?
10. Given that current combination chemotherapy regimens are highly toxic and provided without a clear sense of which patients will respond and which of the component drugs have efficacy in individual patients, how would you develop strategies to reduce or replace these front-line treatments with more personalized therapies?

Supplementary Sidebars

Supplementary Sidebar 17.1 Modern cancer therapies have had only a minor effect on the overall death rate from the disease

It is instructive to examine the causes of declining rates of cancer-associated mortality and their connection with improvements in detection and therapy, the latter including surgical resection of primary tumors as well as various forms of chemo- and radiotherapy. Figure 17.1 reveals that stomach cancer—once a major killer—has declined by a factor of more than 6 in the United States over the past 85 years, an apparent reflection of better food storage and preservation practices and associated declines in fungal contamination; declines in *Helicobacter pylori* infection rates may also have contributed to this decrease. Deaths from carcinomas of the uterus and lower intestinal tract have declined because of increased screening using the Pap smear and colonoscopy, respectively; these have allowed early-stage tumors to be removed before they became malignant. Lung cancer mortality in males has begun to decrease because of declining rates of tobacco use. (In the United States, in the years 2004–2008, 20% of the overall decline in cancer-associated mortality came from decreases in lung cancer–associated deaths, which resulted almost entirely from reductions in smoking.)

None of these important declines in death rate seems to be attributable to improved therapeutic treatment of established aggressive cancers. For example, 236,000 new cases of lung and bronchus cancer were predicted to occur in the United States in 2021, while mortality associated with this disease was expected to be 132,000. About 60,000 new cases of pancreatic cancer were anticipated, with 48,000 associated deaths. Diagnosed cases of liver cancer and associated mortality were predicted to be almost 42,000 and 30,000, respectively. Hence, diagnosis of these killer diseases continues to carry a very poor prognosis.

Figure 17.1B reveals that most of the major sources of cancer-associated mortality have remained steady or increased somewhat. Notable exceptions are breast and prostate cancers, where age-adjusted mortality rates have declined 25–30% over the past two decades—clear tributes to the effectiveness of modern therapeutic attacks on these tumors; the major causes of this improvement appear to be traceable to surgery, adjuvant chemotherapy (that is, treatment with cytotoxic drugs following surgery), and adjuvant radiotherapy, as well as tamoxifen and anti-androgen treatments, and, in the case of breast cancer, Herceptin, cessation of hormone-replacement therapy, and, quite possibly, increased screening by mammography.

Still, as outlined above, the decline in overall cancer mortality cannot be attributed to therapeutic attack on advanced tumors. Instead, these statistics indicate that prevention strategies (including lifestyle changes) as well as screening for certain types of cancer are likely to yield the greatest benefits in reducing deaths from cancer, at least for the foreseeable future. They also hint at the considerable challenges still facing the researchers who are developing therapeutics directed against already-established aggressive primary tumors and derived metastases.

Supplementary Sidebar 17.2 Clinical practice and our understanding of disease pathogenesis have often been poorly aligned, leading to sub-optimal, often tragic outcomes

The treatment of breast and prostate cancers over the past century reveals the strong disconnect between how cancers develop and how they have been treated. To begin, we recognized the overriding fact that virtually all breast and prostate cancer–associated mortality derives from metastases, not from the outgrowth of primary tumors. Hence, much attention has been focused on preventing the dissemination of cancer cells and the outgrowth of metastases.

Radiotherapy was used sporadically throughout much of the first half of the twentieth century to treat various types of cancer. In the case of breast cancer, however, surgery was the treatment of choice until the 1980s. In 1894, two American surgeons—Willy Meyer in New York and William Halsted in Baltimore—simultaneously reported the procedure that came to be called the *radical mastectomy*. It involves excision not only of the entire breast in which a tumor has been detected but also of underlying chest wall muscles and nearby lymph nodes, including those in the armpit. Until the 1970s, as many as 90% of women treated surgically for breast cancer in the United States underwent this procedure. In addition to disfigurement, a significant percentage of treated women experienced lymphedema caused by the inability of lymphatic fluid to properly drain from the arm on the side where the axillary (armpit) lymph nodes were excised. In many patients, it was and is a lifelong affliction.

The logic behind radical mastectomy derived from, among others, Rudolf Virchow, the father of modern pathology and the popularizer in 1852 of *omnis cellula e cellula*—all cells arise from other cells, a fundamental concept underlying all modern biology. Virchow argued that the lymph nodes draining a tissue (see Figure 14.42) served as filters to trap disseminating cancer cells. Thereafter, others concluded that metastases growing in these nodes represented staging areas from which a second wave of dissemination would occur to more distant sites in the body, eventually spawning life-threatening metastases. Hence, removal of draining lymph nodes, including those at some distance from the primary tumor, was thought to be a critical means of preventing distant metastatic spread.

This thinking excluded an alternative model of metastasis: that breast cancer cells metastasize simultaneously to draining lymph nodes and to distant tissues. Accordingly, the presence of significant numbers of lymph nodes carrying shed breast cancer cells might be only an indication of a parallel spread of primary tumor cells directly to distant anatomical sites. In effect, according to this parallel dissemination model, the lymph nodes served only as “canaries in the coal mine”—providing signs that distant dissemination had already occurred, rather than being temporary staging areas for more distant travel. If correct, then attempts to prevent metastasis by treating the primary tumor and draining nodes would be doomed to failure.

Beginning in the 1970s, there was increased awareness that the Halsted radical mastectomy might not confer substantial benefit on many breast cancer patients. Although staunchly resisted by American surgeons, who argued that to do less would put breast cancer patients at grave and unnecessary risk, a more conservative procedure termed a *lumpectomy* was developed; it involved removing the tumor and immediately surrounding breast tissue but leaving the remainder of the breast and adjacent tissue intact. Likewise, there was resistance to the notion of conducting a controlled clinical trial, in which the benefits of radical mastectomy versus lumpectomy would be compared in two similarly sized clinical populations.

When such controlled trials were nonetheless performed, it became clear that breast cancer patients fared equally well following a lumpectomy as after radical mastectomy, in terms of their disease-free survival and long-term survival. In aggregate, between 2 and 3 million Halsted procedures were performed in the United States over the course of the twentieth century, and it is plausible that few if any women carrying aggressive primary tumors ever received significant, long-term benefit from this procedure, or at least more benefit than they would have received from the far less disfiguring lumpectomy.

A similar dynamic describes the trajectory of prostate cancer surgery. In this case, a different preconception drove surgical practice: that a high percentage of primary prostate carcinomas have the potential to metastasize. In many clinical practices, however, radical prostatectomy has been pursued as the most prudent means of preventing metastatic relapse for all patients diagnosed with various forms of this disease, including still-benign, localized tumors. In the case of this surgical procedure, the side effects are once again significant: radical prostatectomy often leads to lifelong incontinence and impotence. A 2012 study analyzed the clinical outcomes of prostate cancer patients with localized, still-benign tumors who were treated with radical prostatectomy or, alternatively, underwent “watchful waiting,” that is, periodic monitoring of the prostate gland in the years after initial diagnosis. This study demonstrated that the prostate cancer–associated mortality in the decade following surgery was essentially equivalent for both those who did and those who did not undergo prostatectomy. Its conclusions need to be qualified because patients who have

low-grade tumors (and represent the great majority of prostate cancer patients) are not likely to benefit from prostatectomy, whereas a minority—those with high-grade, malignant tumors—may receive substantial benefit.

The breast and prostate cancer treatments cited above are clearly influenced by the concept that most primary tumors that are detected will sooner or later become aggressive. For example, many medical and surgical oncologists express the clear opinion that invasive breast cancers, if left untreated, will inevitably develop into large, life-threatening malignancies that can no longer be controlled by available therapies. Hence, in the absence of any clinical intervention, rather than the 39,500 breast cancer–related deaths that were predicted to occur in 2012, there might be 227,000 deaths—the number of invasive breast cancers that were predicted to be diagnosed in the United States that year.

Breast oncologists will also argue that small tumors, if treated early, are curable, whereas large tumors are far less curable and more prone to generate metastatic relapses. This thinking is once again strongly influenced by the mechanistic model in which all small tumors expand sooner or later into large, clinically significant tumors. The alternative to this thinking is radically different: most small tumors will never develop into large, life-threatening growths within the expected lifetimes of patients. With diagnostic imaging technology that detects tumors of smaller and smaller size, most of the currently detected breast cancers may well fall into this second class.

Moreover, the “curability” of small tumors implies that if they are caught early, they can be successfully treated. The alternative explanation is that it is unimportant when these small tumors are detected during the course of their development, because their small size testifies to their intrinsic indolent nature and “curing” them represents the elimination of growths that would never become life-threatening, whether or not they had been detected in the first place. The current inability to predict accurately whether a given tumor will or will not eventually become life-threatening means that in the United States virtually all breast cancers that are detected are treated aggressively with chemotherapy (including, when appropriate, tamoxifen and Herceptin) and radiotherapy as well as surgery. Importantly, the above conjectures on the nature of breast and prostate cancer progression remain topics of heated debate.

Supplementary Sidebar 17.3 The ability to assign tumors to specific disease subtypes is critical to the success of drug development

Tumors that have traditionally been placed together in a single group, such as leukemias, constitute a very heterogeneous collection of diseases, each having its own route of pathogenesis, its own set of acquired genetic and epigenetic alterations, and its own distinct responses to a particular therapy. For example, the actions of Gleevec

(also known as Glivec and imatinib), a drug discussed extensively in this chapter, are focused on antagonizing, among several molecular targets, the Bcr-Abl oncoprotein, which is found in virtually all (>95%) cases of chronic myelogenous leukemia (CML) but is uncommon in most other kinds of leukemias (see Figure 4.11). During its initial clinical development, Gleevec might well have been tested in patients suffering from all types of leukemia, in which case 5% or less of the treated population (that is, the 5% suffering from CML) would have been found to benefit from this therapy—a success rate that is usually far too low to justify further investment in the development and clinical introduction of a drug.

Instead, in early clinical trials, Gleevec treatment was limited to only those patients whose leukemias had been certified to carry the specific chromosomal translocation that is the hallmark of CML and causes production of the Bcr-Abl oncoprotein. This strategy yielded extremely favorable clinical responses in the great majority of treated CML patients, which encouraged its further, accelerated development and its rapid introduction into oncology clinics worldwide.

(As an aside, Gleevec's early and resounding clinical successes in the late 1990s were viewed as a harbinger of things to come—a strong argument for the powers of rationally designed drugs. As it turned out, CML is a rather unique condition, in that the chronic phase of this disease seems to be driven entirely by the Bcr-Abl oncoprotein, making the leukemia cells highly vulnerable to the shutdown of this protein. This contrasts with most adult neoplasias, in which complex genetic alterations are present in the cancer cells' genomes and multiple, distinct oncogenic events collaborate to drive disease progression, as discussed in Chapter 11. The multiple genetic alterations and the plasticity of the genomes of the cells forming the more common tumors appear to underlie their far lower response rates—and the lower reductions in disease-related mortality—following administration of a variety of newer rationally designed drugs. Hence, most unfortunately, the brilliant success of Gleevec did not foretell similar successes of other targeted drugs in the years that followed.)

Supplementary Sidebar 17.4 Prostate cancers usually do not require aggressive intervention—a tale of two countries

By some estimates, the percentage of elderly American men harboring prostate carcinomas, as judged upon autopsy, is roughly equal to their age in years. Thus, even though almost 80% of American men develop prostate carcinomas by the age of 80 (as judged upon autopsy), only about 3% of them die of the disease. In many American states, the number of cases of prostate cancer diagnosed each year (in men of all ages) exceeds by a factor of about 6 the number of deaths caused by this disease.

In very large part, these large numbers of registered cases (that is, disease *incidence*) are artifacts of diagnostic bias—reflections of our improved ability to detect neoplasms whose existence would previously have gone unnoticed because they would not have progressed to life-threatening malignancies (**Figure S17.1**). For example, in countries such as Denmark, where screening for prostate cancer using the prostate-specific antigen (PSA) blood test was uncommon, the estimated age-adjusted annual incidence rate of this tumor was 31 cases per 100,000 in the year 2000, whereas in the United States, where use of this test was widespread, the registered incidence was 104 per 100,000 that year. (In one large study cohort in the United States, the proportion of patients bearing tumors that suggested low risk of invasion and metastasis rose from 29.8% in 1989–1992 to 45.3% in 1999–2001.) Because clinicians have been unable to accurately discriminate between tumors that require therapy and those growths that can be left alone, aggressive treatment of diagnosed tumors became the norm in the United States. By one estimate, fewer than 10% of patients with prostate cancer in the United States are subjected to "watchful waiting," that is, no immediate clinical treatment with periodic surveillance every several years. In contrast, watchful waiting has been the norm in Denmark with relatively little value attached to aggressive treatment of the great majority of growths detected in the prostate.

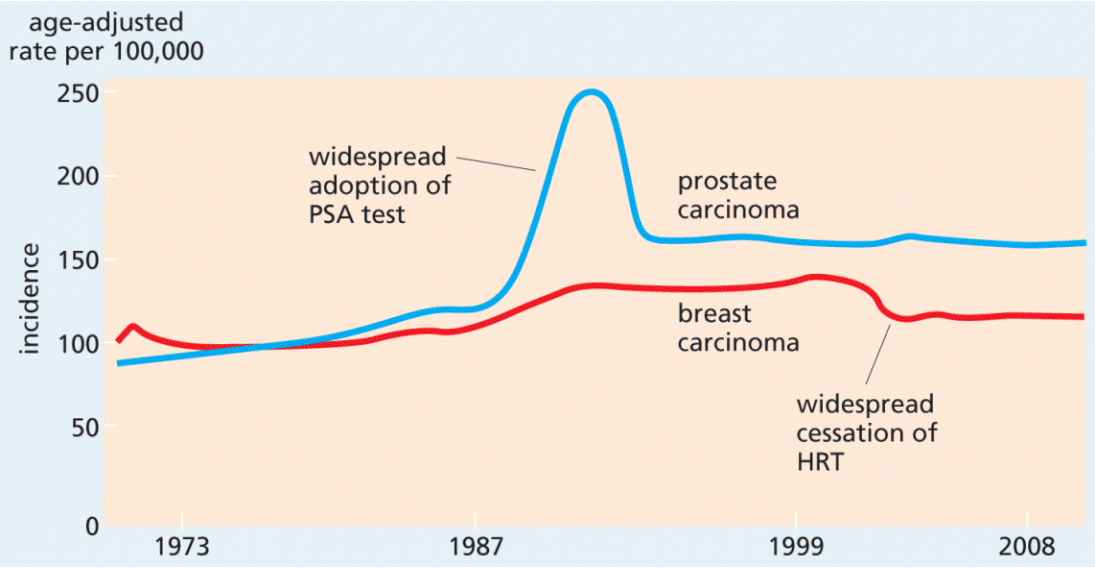

Figure S17.1 Incidence of prostate vs. breast carcinomas in the United States
The incidence of prostate cancer briefly and abruptly increased in the United States in 1991–1992, when a clinical report demonstrating the utility of testing for serum levels of prostate-specific antigen (PSA) was published, leading to the test's widespread clinical adoption. Shortly thereafter, the disease rate returned to its historic, gradually increasing trend, indicating that the spike in prostate cancer incidence was an observational (i.e., diagnostic) artifact rather than a reflection of changes in the real frequency of life-threatening disease. By 2007, an estimated 20

million PSA tests were being performed annually in North America. Five years later, the lifetime risk of an American man being diagnosed with prostate cancer was ~16%, whereas the risk of dying from this disease was 2.9%. Similar dynamics have governed breast cancer incidence, which peaked at 142 (age-adjusted) cases per 100,000 population in 1999. (Here there was also a dramatic readjustment of incidence, but one traceable to a real biological process: the impressive decrease of ~7% in breast cancer incidence observed between 2002 and 2003 was attributed to widespread reduction in the use of hormone replacement therapy, or HRT.) By 2012, it was concluded that PSA testing had measurable benefit only for younger men with a longer life expectancy and that for all others, the disadvantages of this test (resulting from the morbidity caused by aggressive clinical treatment following positive PSA test results) outweighed the potential benefits. (Before 1999, from A. Jemal et al., *CA Cancer J. Clin.* 55:10–30, 2005.)

Still, the aggressive overtreatment practiced in the United States compared with the watchful waiting practiced until recently in Denmark has had significant differential effects on the age-adjusted prostate cancer–associated mortality rates: it declined by >25% in the United States during the period 1975–2005 while having increased by ∼50% during this period in Denmark. Averaged over the 2000–2006 period, the prostate cancer–associated mortality rate was ∼75% higher in Denmark than in the United States. Taken together, these numbers suggest that even though the great majority of prostate cancer patients in the United States are treated with one or another form of unnecessary therapy, this aggressive scattershot approach to treating almost all men diagnosed with prostate cancer—treating many who do not really require aggressive treatment along with the few that do—has yielded substantial benefits in terms of reducing age-adjusted mortality associated with this disease.

Supplementary Sidebar 17.5 *p53* germ-line polymorphisms and somatic mutations can complicate the induction of apoptosis by drugs

The induction of tumor cell apoptosis by anti-cancer drugs is often influenced by the configuration of the *p53* gene in a patient’s tumor genome. Thus, in addition to the somatic mutations that have altered this gene during the course of tumor progression, the inherited germ-line version of *p53* may affect responsiveness to treatment. Indeed, it is possible that, in general, the configuration of the *p53* alleles in a patient’s tumor represents the single most important determinant of responsiveness to various forms of therapy.

To begin, we note that the “wild-type” human gene comes in two polymorphic variants that affect the identity of the amino acid in residue position 72 of the p53 protein; one encodes arginine (72R) and the other specifies proline (72P). Cultured, otherwise isogenic cells that express the 72P, the 72R, or no p53 protein exhibit dramatic differences in their apoptotic responses following exposure to two commonly used chemotherapeutic drugs (**Figure S17.2A**). And patients whose tumors retained the two copies of the wild-type 72R allele showed substantially greater survival than those whose tumors carried a wild-type 72P allele (see Figure S17.2B). Observations like these point to challenges in the development of apoptosis-inducing therapies that reflect a patient’s inherited germ-line alleles.

Figure S17.2 Effects of p53 polymorphisms on the induction of apoptosis (A) Human H1299 lung cancer cells, which have lost expression of their endogenous *p53* gene, were forced to express either the 72P or the 72R polymorphic variant of wild-type human p53 protein. They were then exposed to various concentrations of cisplatin (*left*) or doxorubicin (*right*), two commonly used anti-tumor chemotherapeutic drugs (see Tables 16.1 and 16.2), and their survival following drug-induced apoptosis was gauged. Note that the ordinate is a logarithmic scale. As is apparent, those cells that expressed the 72R variant of p53 were far more sensitive to killing by both agents than were those expressing the 72P variant protein. Moreover, as anticipated, those expressing no p53 protein were far more resistant to killing by both agents. (B) In this study, 70 patients suffering from inoperable head-and-neck squamous cell carcinomas (HNSCCs) were treated with cisplatin. Of those patients, 48 carried tumors with wild-type *p53* alleles (either 72P or 72R heterozygotes or homozygotes). Of these, 31 had tumors that were of the 72R/72R genotype, 12 had tumors of the 72P/72P genotype, and 5 had tumors

of the 72P/72R genotype. The survival of these three groups is shown here. Those patients who were R/R homozygotes (whose p53 proteins favored drug-induced apoptosis—see Panel A) enjoyed far better survival than those with the other two genotypes. (C) For the 70 patients mentioned in panel B, the survival of the *p53*-positive and -negative groups in the years following initial diagnosis and treatment is shown in this Kaplan–Meier plot. Hence, independent of the germ-line configuration of their *p53* alleles, retention in their tumors of a wild-type gene copy (either the P or R allelic variant) was associated with far better long-term survival than was a state in their tumors in which both wild-type gene copies were lost. (Subsequent research on a larger group of patients has extended these results and solidified the conclusions, having made them statistically more robust.) (D, E) The responses to chemotherapy and thus survival of breast cancer patients are shown here in these Kaplan–Meier graphs, in which the patients are segregated according to the *p53* and *ATM* status of their tumor cells (see Figure 9.9). Their clinical courses can be explained by the responses of their cancer cells to genotoxic chemotherapeutic agents, such as doxorubicin. As is apparent, patients whose tumors were *p53* wild-type but lacked ATM function fared far worse than did those whose ATM function was intact. Thus, cancer cells that possessed intact p53 and ATM function were able to respond to chemotherapy by activating a cytostatic or apoptotic response, eliminating these cells and conferring clinical benefit; in contrast, those with defective ATM function could not activate their p53 apoptosis-inducing protein, thereby permitting these cells to survive, and leading to a poor clinical course. Conversely, those patients whose tumors lacked p53 function and also lacked ATM function fared far better than those whose tumors lacked p53 but expressed wild-type ATM. In this case, it seems that in the absence of these two DNA damage–response proteins, cancer cells that were exposed to genotoxic chemotherapeutic agents lacked critical G_1/S and G_2/M cell cycle checkpoint controls (see Figure 8.4). Following chemotherapy-induced DNA damage, their cancer cells, rather than halting and repairing this damage, proceeded to advance into M phase, thereby stumbling into mitotic catastrophe (see Figure 17.10); the resulting death of these cancer cells explained the better clinical course of these patients. In contrast, in the presence of functional ATM, p53-mutant breast cancer cells still retained a critical checkpoint control protein, enabling these cells to halt cell cycle advance in response to DNA damage and repair their DNA before they re-entered the cell cycle; this exit from the cell cycle allowed the cancer cells to survive and, subsequently, proliferate, resulting in the poor clinical course of these patients. (A–C, from A. Sullivan et al., *Oncogene* 23:3328–3337, 2004. With permission from Nature. D and E, from H. Jiang et al., *Genes Dev.* 23:1895–1909, 2009. With permission from Cold Spring Harbor Laboratory Press.)

The somatic mutations that affect p53 also are determinants of a tumor's responsiveness to chemotherapeutic drugs and thus the clinical course of the patients carrying these cancers. As is indicated in Figure S17.2C, the retention of a wild-type *p53* allele in patients' head-and-neck squamous cell carcinomas dramatically improved overall survival.

Actually, p53 can have conflicting effects on responsiveness to chemotherapeutics, depending on the status of other genes in the signaling network with which it interacts. In particular, the ATM protein, which is responsible for activating wild-type p53 protein in response to DNA damage (see Figure 9.9), is an additional important factor that operates together with p53 to determine responsiveness to cytotoxic drugs that target the DNA of cancer cells (see Figure S17.2D and E).

Taken together, these diverse observations lead to the conclusion that p53 (and ATM) are critical regulators of cancer cells' responses to chemotherapy, and that these responses are shaped by both the germ-line configuration of the genes that encode these proteins and the somatic mutations that alter these key regulators.

Supplementary Sidebar 17.6 Chemical synthesis, compound libraries, and high-throughput screening can identify lead compounds for further clinical development

Currently available synthetic organic chemistry techniques make it possible to generate some 10^{200} distinct molecular species by linking various combinations of chemical groups to one another in various orders and configurations—the technology of "combinatorial synthesis." Of these organic molecules, only a tiny fraction—about 10^{62}—have a molecular weight below 500, and only 1% of these are thought to possess the chemical properties, such as solubility, lipophilicity, chemical stability, and molecular weight, that would make them plausible drug candidates (**Table S17.1**). Instead of exploring the entire, still-huge "chemical space" of 10^{60} organic molecules synthesized by such combinatorial methods (**Figure S17.3A**), it is far more productive in practice to search through collections ("libraries") of compounds that have been synthesized for previous drug development programs and contain, typically, 10^5 or more distinct chemical species. (About a quarter million distinct molecular species are estimated to be present in aggregate in the chemical libraries currently screened by the pharmaceutical industry.) These compound libraries are stored in industrial facilities (Figure S17.3B) from which individual compounds can be retrieved robotically. The technology of *high-throughput screening* (HTS) makes it possible to search through libraries of existing diverse organic molecules in order to find the small number having the functional properties of the desired drug, for example, a chemical species that inhibits a certain tyrosine kinase while leaving other tyrosine kinases unaffected.

Thus, *in vitro* enzymological assays or cell-based assays can be devised in which 10^5 or even 10^6 distinct compounds can be individually assayed, using robotic machinery (Figure S17.3C), to measure a functional property, such as the ability to inhibit the kinase of interest; these screens can often be accomplished in several days.

Table S17.1 Predictors of poor drug absorption

Properties of a molecule that predict its poor absorption or permeation into tissues and cells[a]
1. No more than 5 hydrogen bond donors
2. Molecular weight over 500
3. Octanol/water solvent partitioning >5 (lipophilicity)
4. More than 10 hydrogen bond acceptors (N's and O's)

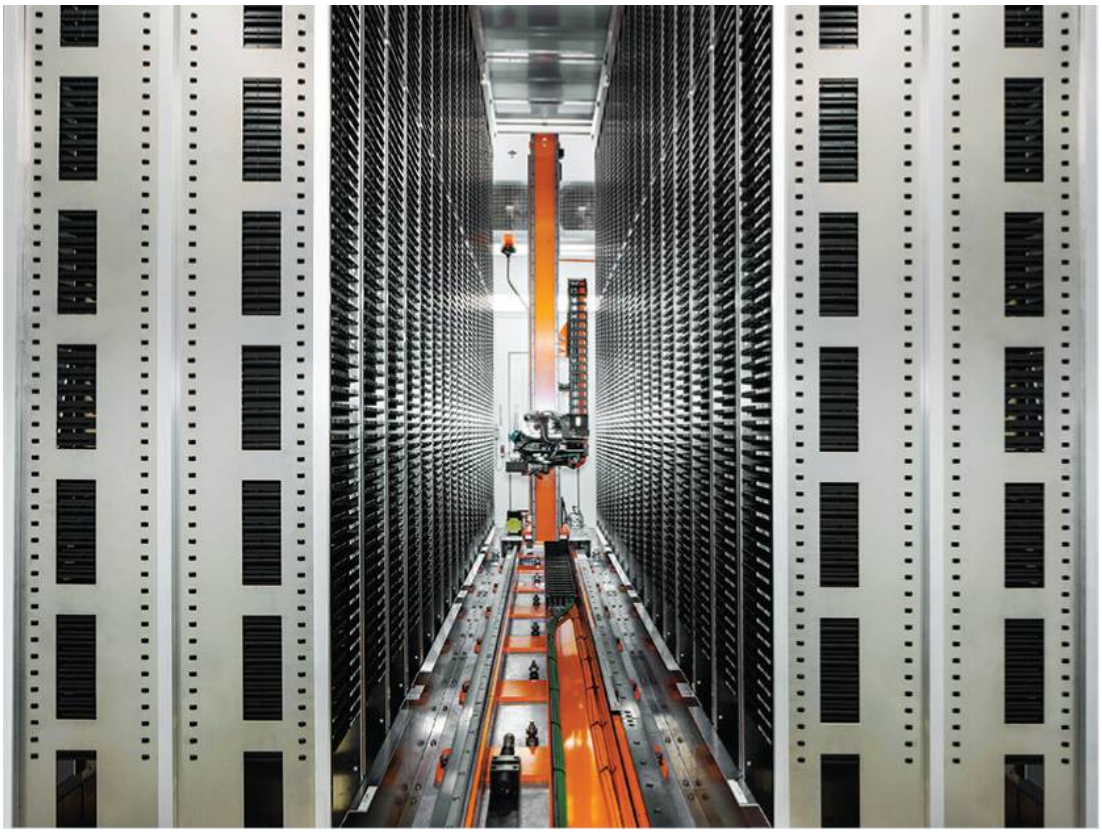
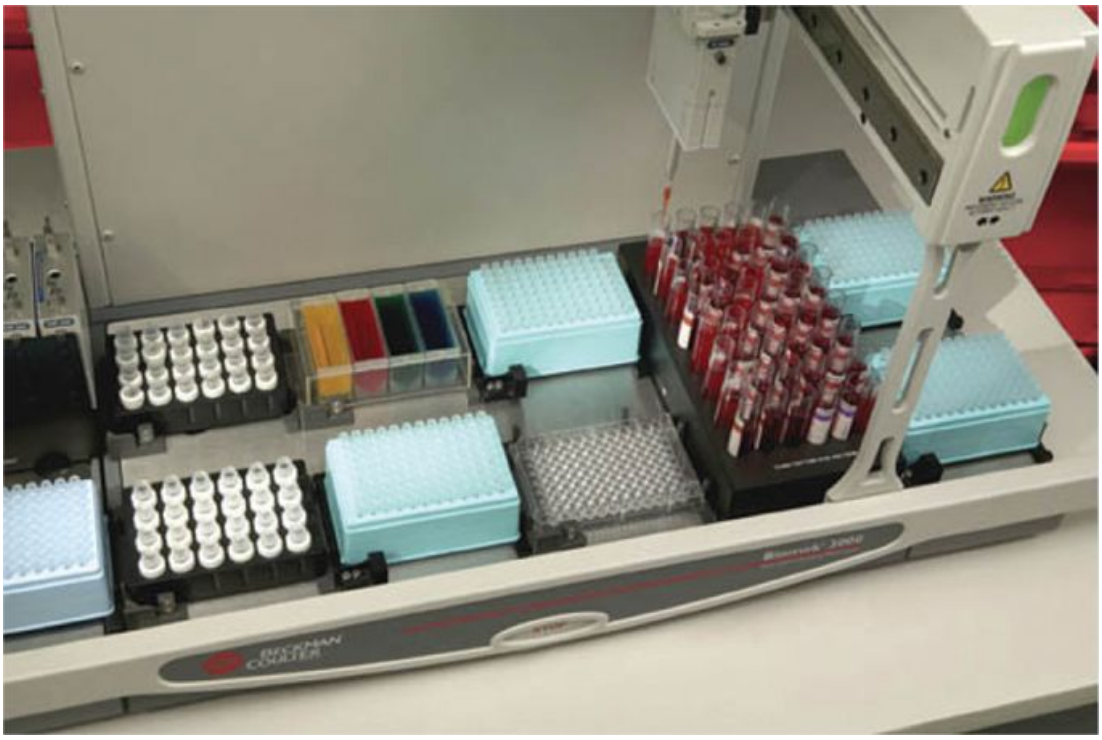
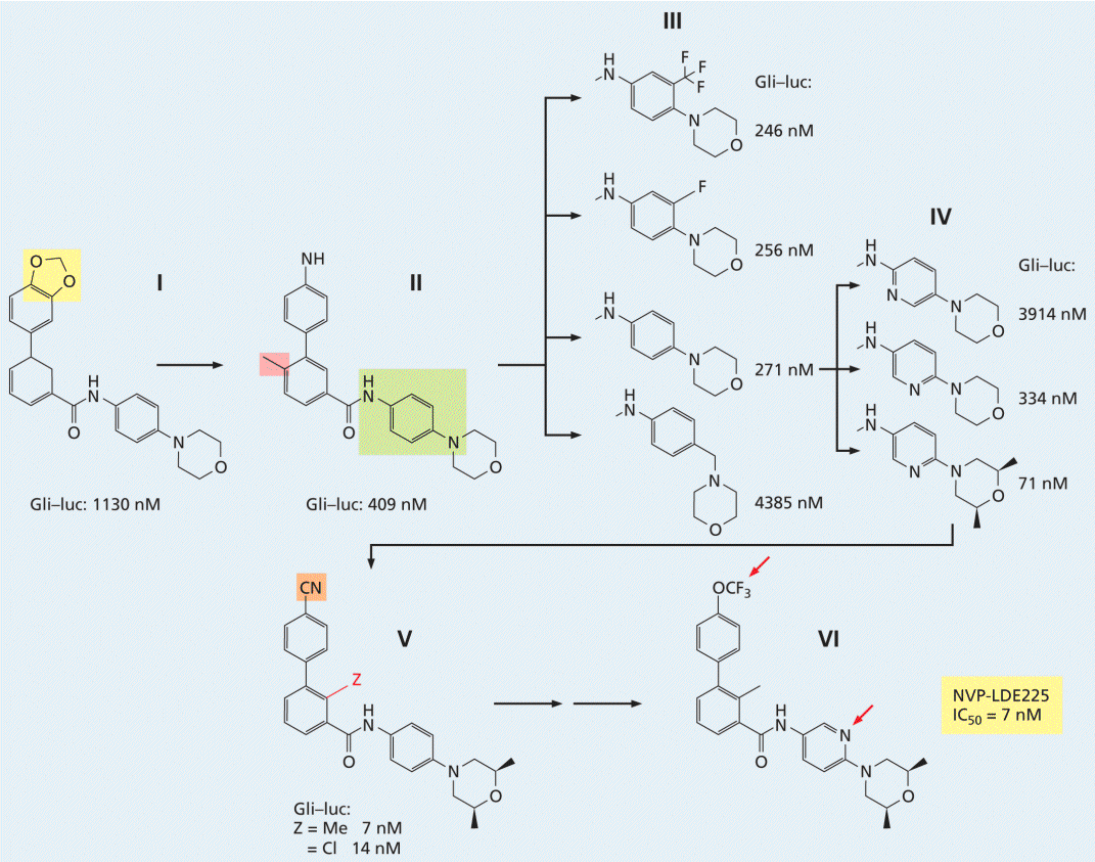
(A)



(B)



(C)



(D)

Figure S17.3 Generation of compound libraries and screening of large numbers of compounds (A) The diversity of chemical species including natural and synthetic organic products can be portrayed graphically by depicting a three-dimensional “chemical space” in which each of the three dimensions indicates a specific chemical attribute (a “descriptor”) of the molecules being cataloged. In reality, because the number of descriptors (each referring, for example, to the presence of a specific side chain in the molecules being plotted) is vastly larger than three, the actual chemical space is multidimensional, amounting possibly to several hundred dimensions. (B) The drug library of a typical large pharmaceutical company is stored, as seen here, in a facility from which individual compounds can be retrieved robotically. (C) Computer-driven robots, such as the one pictured, can be used to process thousands of samples daily, often using the 96-well microtiter plates shown in this photograph. By introducing enzyme- or cell-based assays into these plates, the biochemical and biological activities of large numbers of compounds can be measured over a short period of time—the technology of high-throughput screening (HTS). (D) The optimization of a drug designed to

antagonize Smoothened, as described here, reflects the general strategy of lead-compound optimization. In this case, the drug development began with a lead compound (**I**, *above*, *left*) that had measurable activity against a targeted molecule but only at an unacceptably high concentration (IC_{50}), in this case 1130 nM. (In this case, a cell-based assay was used to evaluate the ability of a test compound to reduce the level of the luciferase protein, expression of which was being controlled by the Gli transcription factor.) Its derivatization began with a major modification of the northernmost ring (*yellow field*) and the addition of a methyl group (**II**, *pink field*) on its western side. Subsequent derivatizations of the area in the *green field* of molecule II yielded four compounds (**III**) that exhibited either substantial increases or minimal decreases in the IC_{50} (concentration needed to achieve 50% inhibition). However, further derivatizations of one of these (IC_{50} of 271 nM) led to three more compounds (**IV**, *far right*), one of which showed an IC_{50} of only 71 nM following the addition of two methyl groups in the southeastern part of this molecule. This improvement was incorporated into the next versions of the drug (**V**, *below left*), which carried two alternative additions. These involved initially removing the previously added methyl group on the western side of the molecule (see **II**) and derivatizing instead the same ring (*side group* Z of *V*) with two alternative side groups (*below*). One of these, involving the addition of a methyl group (Me), yielded a molecule with an IC_{50} of 7 nM. Further derivatizations of the northernmost ring and an alteration of the heterocyclic ring (**VI**, *red arrows*), undertaken to improve pharmacokinetics and oral bioavailability, yielded the final drug molecule, termed NVP-LDE225. This drug was then introduced into pre-clinical studies focused on the treatment of small-cell lung cancer (SCLC) and medulloblastoma. (A, courtesy of S.L. Schreiber. B, courtesy of Novartis Pharma AG. C, courtesy of Beckman–Coulter Co. D, from S. Pan et al., *ACS Med. Chem. Lett.* 1:130–134, 2010. With permission from American Chemical Society.)

High-throughput screening of such libraries often yields a small number of *lead compounds* that have some of the desired functional and chemical properties. Researchers can then explore the chemical space in the immediate vicinity of a lead compound by incrementally modifying it, doing so by adding certain chemical groups to the initially identified molecule and removing others. This process of derivatizing a lead compound may result in the discovery of variant chemical structures with even better properties, such as improved solubility, ability to inhibit a targeted enzyme at lower concentrations, improved permeation into cells, or the ability to be taken orally (Figure S17.3D). However, even with such modifications of existing compounds, only tiny corners of the total chemical space of 10^{60} possible drug compounds have been explored by the pharmaceutical industry.

Supplementary Sidebar 17.7 Evolution can generate huge collections of structurally similar proteins

Evolution generally proceeds via the incremental modification of existing morphological structures or existing molecules. In the case of the latter, the invention of totally novel protein structures is a very rare event, even when measured over the course of hundreds of millions of years. Accordingly, the structures of almost all modern metazoan proteins are clearly discernible in the proteins encoded by the genomes that served as the common ancestors of modern metazoa. Therefore, once a protein structure is invented and achieves functional activity, the overall molecular scaffold of its evolutionarily derived relatives usually remains relatively unaffected, although small domains or individual amino acids may be altered in these derived proteins to generate novel functions or activities.

This specialization and acquisition of novel function usually depends, over the course of evolutionary time periods, on repeated cycles of gene duplication followed by sequence divergence of the duplicated genes. Thus, each of the resulting diverged genes will specify a protein that has its own distinctive features but nonetheless continues to exhibit the basic, commonly shared structure. In the case of the functionally diverse set of kinase molecules, almost all members of the vast repertoire of modern mammalian kinases can trace their ancestry to a common founder enzyme that must have developed long before the Cambrian era and thus before the metazoan radiation (**Figure S17.4**).

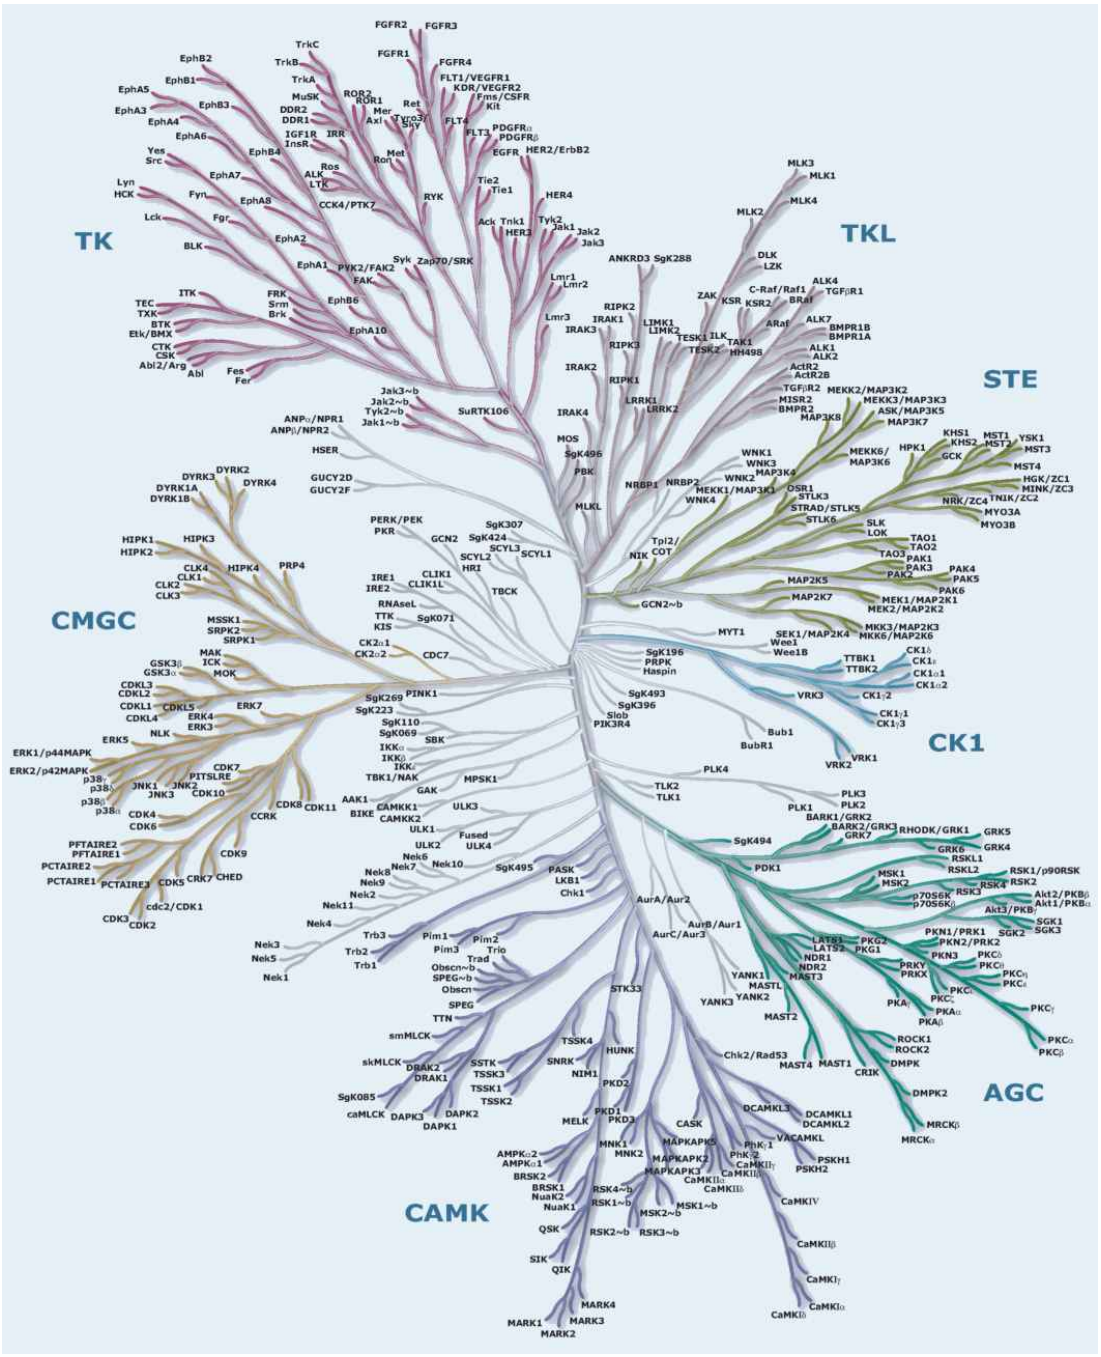


Figure S17.4 The human kinome As illustrated here, the great majority of the protein kinases of mammalian cells, including serine/threonine and tyrosine kinases, share substantial structural similarity, indicating that they all descend from a primitive protein kinase that existed long before the radiation of metazoan life forms. The serine/threonine and tyrosine kinases diverged from one another relatively early and have been further diversified over the past approximately 10^9 years. Altogether, the human genome sequence reveals 518 distinct genes encoding protein kinases, which, as a group, have been called the “human

kinome." Of these, 90 phosphorylate tyrosine residues, and the remainder phosphorylate serine or threonine residues of substrate proteins. All tyrosine kinases (TKs) and 318 serine/threonine kinases show clear structural relatedness to one another and can be arrayed on an evolutionary tree that depicts how they appear to have evolved from one another through repeated gene duplications followed by diversification. (A small number of "atypical" protein kinases, *not shown*, appear to represent independent evolutionary inventions.) The shared origins of the kinases located on this tree dictate that many of these enzymes are structurally similar to one another, which complicates the creation of drugs that interfere selectively with only a few members of this large family of enzymes. The TKs (*top left*) represent relatively recent evolutionary inventions, as they are absent in prokaryotes and are present in only very small numbers (e.g., 3) in the genomes of single-cell eukaryotic protozoa sequenced to date. Their great diversification and specialization appear to have been critical to the evolution of anatomically complex metazoa. The remaining groupings on this tree are TKL, tyrosine kinase-like; STE, homologs of yeast sterile 7, 11, and 20 kinases; CK1, casein kinase-1; AGC, members of protein kinase A, kinase G, and kinase C families; CAMK, calcium/calmodulin-dependent protein kinases; and CMGC, containing CDK, MAPK, GSK-3, and CLK families. (Courtesy of Cell Signaling Technology, Inc.)

Supplementary Sidebar 17.8 Large-scale screening can systematically interrogate the inhibitory effects of a drug on many kinases

Attempts at identifying all of the kinases that might be affected by a drug of interest have, until recently, involved assays of the responses of only a small proportion of the large cohort of protein kinases known to be present in human cells. Consequently, over the past decade, certain off-target effects are likely to have eluded drug developers. This has begun to change with the advent of more systematic screening of a far larger portion of the kinases that might be affected by these inhibitors.

One biotechnology company has developed an assay for measuring the binding affinities of a test drug for 442 distinct kinases that are located on various branches of the kinome tree (**Figure S17.5A–D**). As gauged by this assay, two EGF receptor inhibitors—Iressa and Tarceva—are indeed found to bind preferentially the EGF-R tyrosine kinase, whereas staurosporine, which is thought to inhibit a wide spectrum of protein kinases of all types, is confirmed to exhibit a wide-ranging kinase-binding ability. (The *binding affinity* of a test drug for a kinase, as measured in this assay, has been found to predict the ability of this drug to *inhibit the activity* of the kinase.) This assay can be scaled up to enable the systematic screening of large numbers of kinase inhibitors, which greatly accelerates the rate at which candidate drugs of this class can

be evaluated for their potency and their specificity in targeting a kinase of interest, while having minimal effects on other closely related kinases (Figure S17.5E).

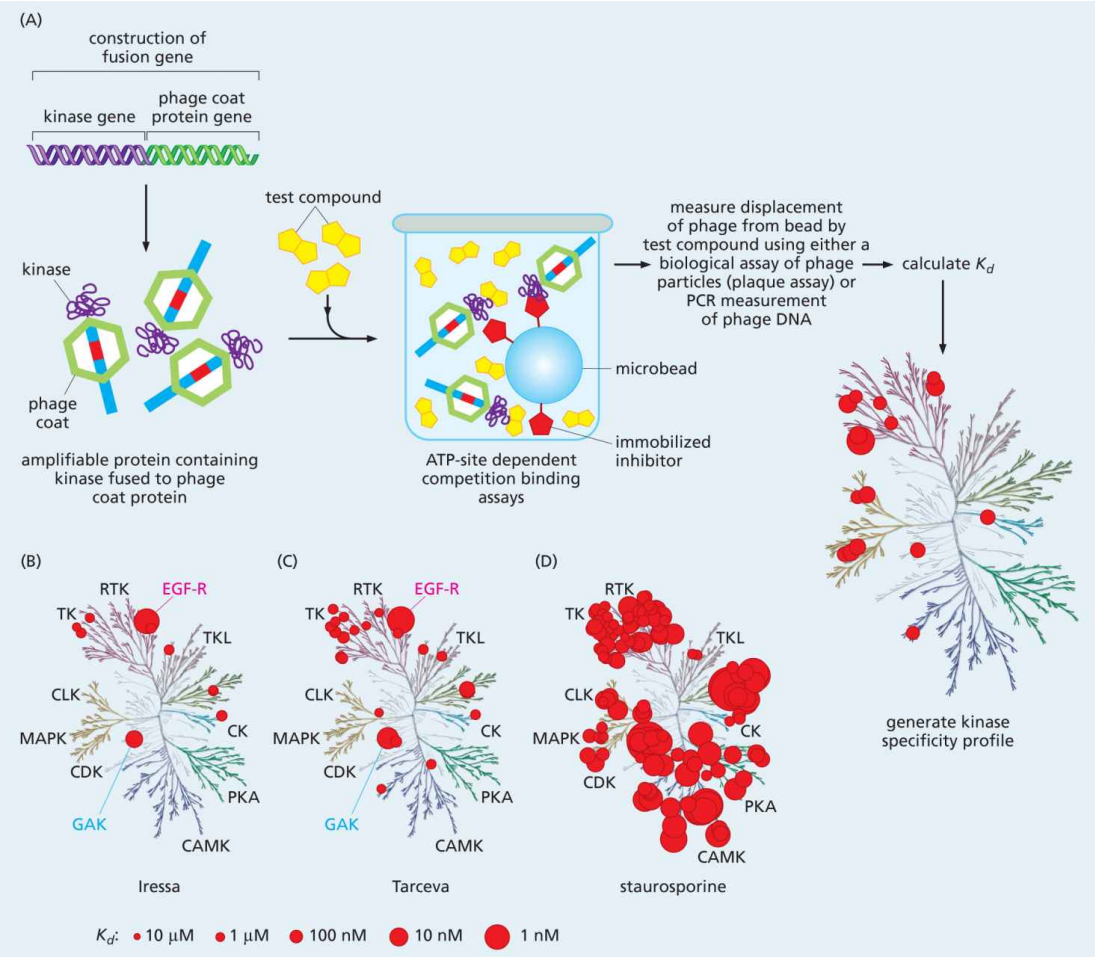

Figure S17.5 Effects of kinase inhibitors on a wide spectrum of protein kinases The individual responses to various kinase inhibitors of an array of 156 distinct tyrosine and serine/threonine kinases have been tested by measuring the *binding affinities* of each inhibitor for each of these kinases. This test depends on the fact that almost all kinase inhibitors bind to the ATP-binding sites of targeted enzymes. (A) A cDNA encoding the kinase domain o a protein is cloned into a bacteriophage vector so that some of the phage capsid (coat) proteins (*green*) are synthesized as fusion proteins with the kinase (*purple*). An ATP analog that is known to bind the ATP-binding sites of many kinases (*red pentagons*) is then immobilized by being linked to microbeads (*light blue*). This allows phage particles to become linked via the fusion proteins in their capsids to the ATP analog on the beads. The assay then measures the ability of a test compound (e.g., a candidate tyrosine kinase inhibitor, *yellow*) to compete with the immobilized ATP analog (*red*), thereby blocking association of the phage to the bead. The number of phage particles

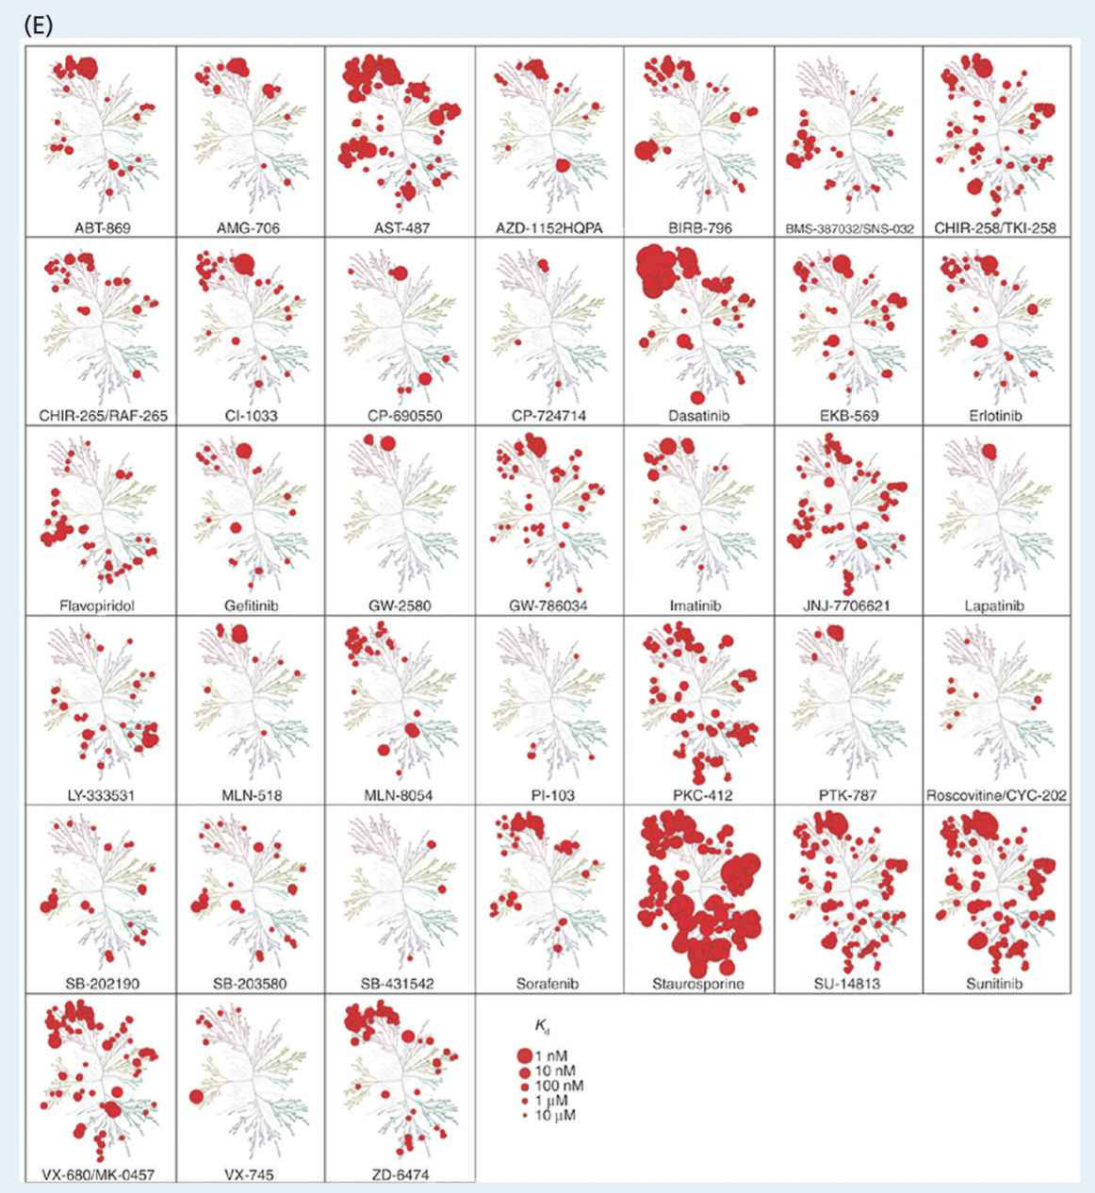
released from the beads (determined by using a phage plaque assay or a polymerase chain reaction for the phage DNA) indicates the reduction in binding of the phage to the beads and therefore the binding affinity of the test compound for the kinase present in the fusion protein. The binding affinity is represented by the displacement constant K_d for the fusion protein, that is, the concentration at which 50% of the phage is displaced from the beads. The remaining panels show the evolutionary relationships of the kinases in the form of kinome trees (see Figure S17.4) on which the binding affinities of tested inhibitors for the kinases are noted. Each kinase that showed a K_d of less than 10 μM is indicated by a red circle whose diameter varies inversely with the K_d (binding affinity constant). (B, C) These panels show the effects of Iressa and Tarceva, respectively, two inhibitors of the EGF receptor (EGF-R) that have already been licensed for clinical use. Both, reassuringly, show greater specificity for the EGF-R than for the 155 other kinases tested. However, Iressa also binds GAK (cyclin G–associated kinase; see Sidebar 5.2) at about a tenfold higher concentration, whereas Tarceva affects GAK at an even lower concentration, barely higher than that required to inhibit the EGF-R itself. (D) In contrast, staurosporine, a widely used experimental reagent that is thought to inhibit many kinases, is seen here to indeed bind a large number of these enzymes, some while it is present at subnanomolar concentrations. (E) The technology described here has been extended to systematically survey the effects of 38 kinase inhibitors, one of which (staurosporine) was analyzed in panel D. (A, from J.D. Griffin, *Nat. Biotechnol.* 23:308–309, 2005. With permission from Nature. B–D, courtesy of P.R. Zarrinkar and D.J. Lockhart; see also M.A. Fabian et al., *Nat. Biotechnol.* 23:329–336, 2005. E, from M.W. Karaman et al., *Nat. Biotechnol.* 26:127–132, 2008. With permission from Nature.)



Supplementary Sidebar 17.9 Epidermal growth factor receptor expression levels predict little about a tumor's susceptibility to receptor antagonists

Elevated expression of the EGF-R is seen in a diverse array of tumors, including glioblastomas, head-and-neck squamous cell carcinomas, and bladder, kidney, esophageal, and lung cancers, often without associated amplification of the encoding gene. In many of these cancers, autocrine signaling loops driven by ligands such as TGF-α and amphiregulin are also activated. Tumors displaying elevated EGF-R expression or activity would seem to be obvious targets for treatment with receptor antagonists, specifically anti-receptor monoclonal antibodies and tyrosine kinase

inhibitors. However, the clinical results of such attempts to date have been disappointing.

In colorectal cancers (CRCs), for example, the responsiveness of a tumor to monoclonal antibody (MoAb) therapy is not predicted by the extent of receptor overexpression. And although colorectal cancers as a class have been relatively unresponsive to treatment with low–molecular-weight tyrosine kinase inhibitors, such as Iressa and Tarceva, non-small-cell lung carcinomas have occasionally responded in a striking fashion (see Section 17.14).

In the case of metastatic CRCs, the presence of a mutant K-*ras* allele in the genome of the corresponding primary tumors is a predictor of nonresponsiveness to anti-EGF-R MoAb therapy, and the direct demonstration of the absence of such an allele in a patient's tumor is now a prerequisite in Europe for MoAb treatment of the tumor. Similarly, the presence in the primary CRC genome of mutant, activated B-*raf* and *PI3K* alleles (the latter involving exon-20 mutations) or inactivated *PTEN* alleles has also been associated with poor response to MoAb therapy, as measured by *time to progression* (interval between inception of therapy and evidence of worsening of symptoms and tumor growth) and *overall survival* (percentage of patients surviving at a given time, independent of other clinical responses). Conversely, elevated expression of amphiregulin and epiregulin—two EGF-R ligands—and the implied activation of autocrine signaling loops have been associated with increased time to progression and overall survival. Significantly, in the presence of a mutant, activated K-*ras* oncogene, the expression of these ligands was not predictive of a positive response to MoAb therapy, indicating that the effects of the K-*ras* oncogene dominate and overrule any other factors that might affect responsiveness to antibody therapy.

In the case of anti-EGF-R monoclonal antibody therapies, the most useful indicator of a positive clinical response is not some biochemical or genetic marker but rather the skin rash developed by some of the patients under treatment (**Figure S17.6**). Taken together, this large body of clinical experience has not been reassuring for the advocates of rational drug therapy.

Figure S17.6 Skin rash—a surrogate marker for treatment efficacy The responses of most solid tumors to anti-EGF receptor monoclonal antibody therapy have been modest. However, the minority of patients who do show significant clinical responses often develop an acne-like skin rash of the sort seen here. This rash may in some way reflect the importance of the EGF-R in maintaining normal skin, but the precise mechanistic reasons for its correlation with positive clinical responses and its utility as a surrogate marker of tumor-killing activity are obscure. (From K.J. Busam et al., *Br. J. Dermatol.* 144:1169–1176, 2001. With permission from John Wiley & Sons.)

Supplementary Sidebar 17.10 BH3 profiling can measure a cell's propensity to undergo apoptosis in response to therapy

The response of a tumor to a Bcl-2 family member inhibitor will depend on the specific balance between pro- and anti-apoptotic Bcl-2 family members in a cell (see Figures 9.23 and 9.25). In the presence of significant pro-apoptotic stimuli, which exists in many cancer cells, the active expression of anti-apoptotic Bcl-2 family members is necessary to prevent cell death. Thus, unlike normal cells, many cancer cells are teetering precariously on the brink of cell death, and disabling a critical pro-survival pathway may push them over the edge.

The relative propensity of a cell to die following a pro-apoptotic stimulus, as well as the identities of the specific Bcl-2 family members that are promoting cell survival in a given cancer cell type, can be accurately measured using an approach termed BH3 profiling. Here, BH3 peptides corresponding to distinct BH3-only proteins are applied to purified mitochondria or permeabilized cells prepared from a tumor of interest (**Figure S17.7**). The resulting level of cytochrome *c* release determines whether target cells are "primed" for apoptosis and, given the known interaction specificities of

different BH3 peptides, which anti-apoptotic Bcl-2 family members are most critical for the cellular balance of pro- and anti-apoptotic forces.

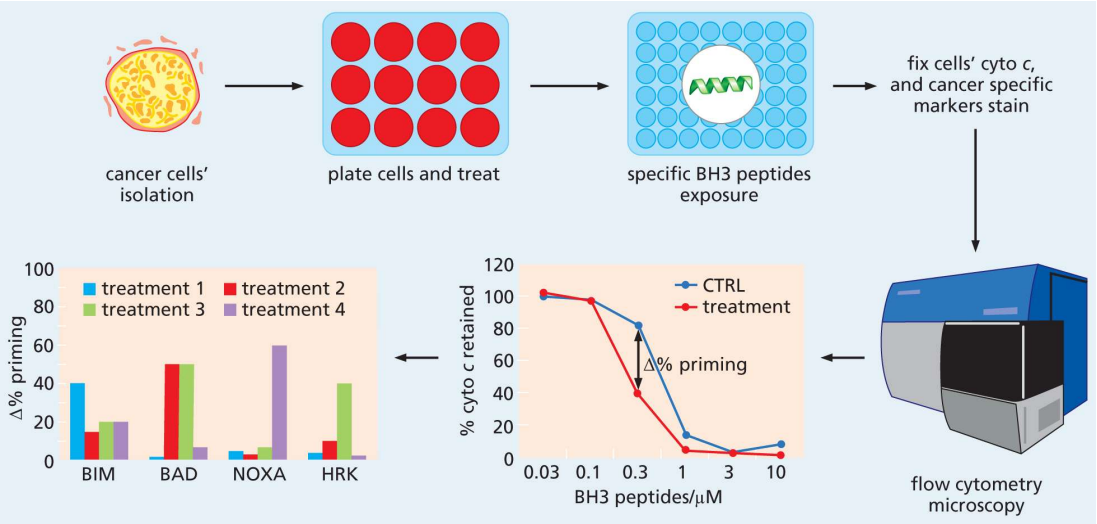


Figure S17.7 Dynamic BH3 profiling The propensity of cancer cells to die in response to specific treatments can be assessed using BH3 peptides. Tumor cells isolated from patients can be treated with a range of cancer therapeutics and then exposed to peptides derived from distinct BH3-only pro-apoptotic regulators. Peptides that effectively push treated cells over the apoptotic threshold promote cytochrome *c* release from mitochondria from treated cells. The level of cytochrome *c* release elicited by each BH3 peptide can be used to define a profile of apoptotic sensitivities that predict response to treatment, changes in apoptotic dependencies following treatment, the effective use of BH3-mimetics as therapeutics, and the response of a given tumor to combinations of BH3 mimetics and specific therapies. (From J. Montero and A. Letai, *Cell Death Differ*. 25, 56–64, 2018. Copyright © 2017, The Authors. This article is available under a Creative Commons Attribution 4.0 International License.)

Results from such experiments not only can identify which tumor types may be amenable to treatment with Bcl-2-targeted therapies, but also can identify tumors that might be responsive to small molecule BH3 mimetics targeting certain Bcl-2 family members. This approach represents a unique type of therapy tailored to a patient's tumor cells, that is, "personalized" anti-cancer therapy. Although one typically seeks a tumor-specific mutation or pathway that demarcates a therapeutic dependency, BH3-profiling provides a *functional readout* that could guide the targeted use of apoptosis-inducing anti-cancer agents.

Glossary

diagnostic bias
: Tendency of an observation or conclusion to be influenced by the specific properties or applications of a diagnostic technique rather than to accurately reflect an intrinsic property of the entity (such as a disease) under examination.

OceanofPDF.com

Footnotes

- aThese rules stipulate that in order for a drug to be orally active, its properties cannot violate more than one of the four listed conditions. Conformance to these rules is said to determine a drug's pharmacokinetics, which derive in turn from (1) its absorption via passive diffusion through mucous membranes and plasma membranes into the general circulation; (2) its distribution via the circulation to various tissues throughout the body; (3) its metabolism, often via cytochromes operating in the liver; and (4) its excretion via the kidneys, gastrointestinal tract, or lungs. In fact, only about half of the drugs that have been approved by the U.S. Food and Drug Administration and are in clinical use conform to these properties, which are often referred to as "Lipinski's Rule of 5" or simply "the Lipinski rules."Return to reference a

GVT graft versus tumor (immunological reaction)

Gy gray (radiation dose unit)

2-HG 2-hydroxyglutarate

5hmC 5-hydroxymethylcytosine

H histone

h prefix referring to the human form of a gene or protein

^{3}**H** tritium

H&E hematoxylin–eosin (tissue stain)

hABH human AlkB homolog

HAMA human anti-mouse antibody

HAT (1) hypoxanthine–aminopterin–thymidine (culture medium); (2) histone acetyltransferase

HB-EGF heparin-binding EGF

HBV hepatitis B virus

HCA heterocyclic amine

HCC hepatocellular carcinoma

hCG human chorionic gonadotropin

HCL hairy-cell leukemia

HCMV human cytomegalovirus

HCV hepatitis C virus

HDAC histone deacetylase

HDM2 human homolog of MDM2

HDR homology-directed (DNA) repair; *also* **HR**

HEK human embryonic kidney (cells)

HER human EGF receptor

HERV human endogenous retrovirus

HES hairy and enhancer of split

HGF hepatocyte growth factor; *also called* scatter factor (SF)

HGFL hepatocyte growth factor-like

HGPRT hypoxanthine guanine phosphoribosyltransferase

Hh Hedgehog

HHV human herpesvirus

HHV-8 human herpesvirus type 8; *also called* Kaposi's sarcoma herpesvirus (KSHV)

HIF hypoxia-inducible (transcription) factor

HIP1 huntingtin-interacting protein-1

HIPK2 homeodomain-interacting protein kinase 2

HIV human immunodeficiency virus

HLA human leukocyte antigen; equivalent to MHC

HMEC human mammary epithelial cell

HMT histone methyltransferase

HNPCC hereditary non-polyposis colon cancer

hnRNA heterogeneous nuclear RNA

HNSCC head-and-neck squamous cell carcinoma

HPE human prostate epithelial (cell)

HPGD 15-hydroxyprostaglandin dehydrogenase

HPRT hypoxanthine phosphoribosyltransferase

HPV human papillomavirus

HR homology-directed (DNA) repair; *also* **HDR**

HRE hormone response element (in DNA)

HRG Heregulin

HRP horseradish peroxidase

HSA human serum albumin

HSC hematopoietic stem cell

HSIL high-grade squamous intraepithelial lesion

HSR homogeneously staining region

MDSC myeloid-derived suppressor cell

MDV Marek's disease virus

MEC mammary epithelial cell

meCpG methyl-cytosine within a CpG dinucleotide

MEF mouse embryo fibroblast

MeIQx 2-amino-3,8-dimethylimidazo[4,5-f]-quinoxaline mutagen

MEK MAPKK/Erk kinase

MEN multiple endocrine neoplasia

MET mesenchymal–epithelial transition; *also* mesenchymal-to-epithelial transition

Met receptor of hepatocyte growth factor

mFISH multicolor fluorescence in situ hybridization

MGMT O^6-methylguanine-DNA methyltransferase; *also called* **AGT**

MHC major histocompatibility complex; *see also* **HLA**

-**mib** low–molecular-weight pharmacologic agent (suffix)

min multiple intestinal neoplasias

MIN microsatellite instability

miRNA microRNA

Miz-1 Myc-interacting zinc finger protein-1

MKP MAP kinase phosphatase

MLKL mixed lineage kinase-like protein

MLL (1) mixed lineage leukemia; (2) myeloid/lymphoid leukemia

MLV murine leukemia virus

MM multiple myeloma

mM millimolar (10^{-3} molar)

MMP matrix metalloproteinase

MMR mismatch repair (of DNA)

mms methylmethane sulfonate

MMTV mouse mammary tumor virus

MNNG *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine

MNU *N*-methylnitrosourea

MoAb monoclonal antibody

moca 4,4′-methylenebis(2-chloroaniline)

MOMP mitochondrial outer membrane permeabilization

mp muscularis propria (of intestinal wall)

mPGES microsomal prostaglandin E2 synthase

MPNST malignant peripheral nerve sheath tumor

MRD minimal residual disease

MRE11 meiotic recombination 11 (protein)

MRI magnetic resonance imaging

MRN MRE11/Rad50/Nbs1 protein complex

mRNA messenger RNA

MSC mesenchymal stem cell

MSH melanocyte-stimulating hormone

MSP methylation-specific polymerase chain reaction

MT middle T antigen of polyomavirus

MT1-MMP membrane type 1-MMP

MTD maximum tolerated dose

mTERT murine TERT

MTH1 mammalian MutT homolog-1

mTOR mechanistic target of rapamycin (kinase)

mTR murine telomerase RNA

MUP major urinary protein

myc (oncogene of) avian myelocytomatosis virus

N ploidy number (where haploid = 1)

N′ (1) N amino terminus of polypeptide; (2) N-terminal (adj.)

NAT *N*-acetyltransferase

NBS1 Nijmegen break syndrome 1

NCAM neural cell adhesion molecule

NCI National Cancer Institute of the United States

NCI-60 Collection of 60 cancer cell lines prepared by the NCI

NECD Notch extracellular domain

neo neomycin

NER nucleotide-excision DNA repair

NES nuclear export signal

NET neuroendocrine tumor

Neu rat ortholog of HER2 (receptor)

Nf/NF neurofibromatosis

NF-κB nuclear factor-κB

NGF nerve growth factor

NGS next generation sequencing

NHEJ nonhomologous end joining

NHL non-Hodgkin's lymphoma

NICD Notch intracellular domain

NK natural killer (lymphocyte)

NKG2D natural killer group 2D (receptor)

NKT natural killer lymphocyte expressing T-cell receptor

NLS nuclear localization (import) sequence

nM nanomolar (10^{-9} molar)

NMR nuclear magnetic resonance

NO nitric oxide

NOD non-obese diabetic

NOD/SCID non-obese diabetic/severe combined immunodeficient (mouse strain)

NotchL Notch ligand

NR no (clinical) response

NRF2 nuclear factor erythroid 2-related (transcription factor)

NRG neuregulin

NSAID nonsteroidal anti-inflammatory drug

NSCLC non-small-cell lung carcinoma

nt nucleotide

NURF nucleosome remodeling factor

4-OHT 4-hydroxytamoxifen

8-oxo-dG 8-oxo-deoxyguanosine

OD optical density

OIS oncogene-induced senescence

OPC oropharyngeal carcinoma

OPG osteoprotegrin (decoy receptor protein)

OPN osteopontin (protein)

ORF open reading frame

OS overall survival

OSCC oral squamous cell carcinoma

OSE ovarian surface epithelium

6-4 PP pyrimidine (6-4) pyrimidinone (photoproduct)

p (1) short arm of a chromosome; (2) probability of an event

Pa Pascal (unit of measured pressure, stress)

PAH polycyclic aromatic hydrocarbon

PAI (1) plasminogen activator inhibitor; (2) pathogenicity-associated island

PAM protospacer adjacent motif (in CRISPR-Cas9 procedure)

PanIN pancreatic intraepithelial neoplasia

PAP prostatic acid phosphatase

PAR-1 protease-activated receptor protein-1 (GPCR)

PARP poly (ADP-ribose) polymerase

PBS phosphate-buffered saline

PCNA proliferating cell nuclear antigen

PCP planar cell polarity

PCR (1) polymerase chain reaction; (2) pathological complete response

PD (1) pharmacodynamics; (2) population doubling; (3) progressive disease

PD-1 programmed death-1 (receptor of T cells)

PDAC pancreatic ductal (exocrine) adenocarcinoma

PDGF platelet-derived growth factor

PDE phosphodiesterase

PDGF-R PDGF receptor

PDH pyruvate dehydrogenase

PDK1 (1) phosphoinositide-dependent kinase 1; (2) pyruvate dehydrogenase kinase 1

PD-L1 ligand of the PD-1 receptor

PDM mean population doublings

PDX patient-derived xenograft

PEG polyethylene glycol

pEMT partial EMT

PEP phosphoenolpyruvate

PET positron-emission tomography

PFS progression-free survival

PGDH 15-hydroxyprostaglandin dehydrogenase

PGE_2 prostaglandin E_2

P-gp P-glycoprotein

PH pleckstrin homology (phosphoinositol-binding protein domain)

PHD proline hydroxylase

PhIP (1) 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine; (2) PH-interacting domain protein

PhK phosphorylase kinase

pI isoelectric point

PI (1) phosphatidylinositol; (2) propidium iodide

PI(3,4,5)P3 *equivalent to* PIP3

PI3K phosphatidylinositol 3-kinase

PIK3CA catalytic subunit of PI3K

PIK3R regulatory subunit of PI3K

PIN prostatic intraepithelial neoplasia

PINCH particularly interesting new cysteine-histidine-rich (adaptor protein)

PIP2 phosphatidyl inositol (4,5) diphosphate/PI(4,5)P_2

PIP3 phosphatidyl inositol (3,4,5) triphosphate/PI(3,4,5)P_3

PK (1) pyruvate kinase; (2) pharmacokinetics

PKA protein kinase A

PKB protein kinase B (=Akt)

PKC protein kinase C

PLC phospholipase C

PLD phospholipase D

PMA phorbol-12-myristate-13-acetate; equivalent to TPA

PMBL primary mediastinal B-cell lymphoma

PML (1) promyelocytic leukemia; (2) progressive multifocal leukoencephalopathy

PND paraneoplastic neurological degeneration

PNI perineural invasion

pol (1) polymerase; (2) retrovirus reverse transcriptase

pol II RNA polymerase II

POT1 protection of telomere 1 (protein)

PP1 protein phosphatase 1

PP2A protein phosphatase 2A

PR (1) progesterone receptor; (2) partial (clinical) response.

PRAS proline-rich Akt substrate

pRb retinoblastoma protein; *also* **Rb**, RB

PRC1 polycomb repressive complex 1

pre-mRNA RNA precursor to mRNA

PRL prolactin

pro-B ALL pro-B-cell acute lymphocytic leukemia

PS phosphatidylserine

PSA prostate-specific antigen

PTB phosphotyrosine-binding (protein domain)

PTC (1) papillary thyroid carcinoma; (2) Patched

PTEN phosphatase and tensin homolog deleted on Chromosome 10

PTH parathyroid hormone

PTHrP parathyroid hormone–related peptide

PTM post-translational modification

PTP phosphotyrosine phosphatase

PUMA p53-upregulated modulator of apoptosis

pY phosphotyrosine

PyMT polyomavirus middle T oncoprotein

q long arm of a chromosome

qPCR quantitative polymerase chain reaction

qRT-PCR quantitative real-time PCR; *see also* **RT-PCR**

r resistant to specified agent

R restriction point (cell cycle landmark)

RA (1) retinoic acid; (2) Ras-association (domain)

Rad radiation repair (gene)

RAE retinoic acid early transcript (ligand)

RAG recombination-activating gene

RANK receptor activator of NF-κB

RANKL ligand of RANK (receptor)

RAR retinoic acid receptor

ras (oncogene of) rat sarcoma virus

RAS protein of *ras* oncogene

Rb retinoblastoma protein

RBD Ras-binding domain

RCC renal cell carcinoma

REF rat embryo fibroblast

relreticuloendotheliosis (oncogene)

RFLP restriction fragment length polymorphism

RFP red fluorescent protein

Rheb Ras homolog enriched in brain

RING really interesting new gene (protein domain)

RIPK receptor-interacting protein kinase

RISC RNA-induced silencing complex

RNAi RNA interference pathway (involving miRNAs, siRNAs, shRNAs)

RNA-seq RNA sequencing (via sequencing of cDNAs)

RNS reactive nitrogen species

ROS reactive oxygen species

RPA replication protein A

RR (1) relative risk; (2) response rate

RSV Rous sarcoma virus

RT reverse transcriptase

RTK receptor tyrosine kinase

RT-PCR reverse transcription PCR; *see also* **qRT-PCR**

S (1) DNA synthesis phase (of cell cycle); (2) Svedberg (unit of sedimentation in centrifuge); (3) serine

S1P sphingosine-1-phosphate

S6 protein 6 of the small ribosomal subunit

S6K1 p70 S6 kinase-1

SA-β-gal senescence-associated β-galactosidase

SAC spindle assembly checkpoint

SAHF senescence-associated heterochromatic foci

SASP senescence-associated secretory phenotype

SC stem cell

SCC squamous cell carcinoma

SCE sister chromatid exchange

SCF stem cell factor

scFv single-chain variable region fragment

SCID severe combined immunodeficiency (syndrome)

SCLC small-cell lung carcinoma

scRNAseq single-cell RNA sequencing

SDF-1 stromal cell–derived factor-1

SDH succinate dehydrogenase

SEM scanning electron micrograph/microscope/microscopy

ser serine

SERM selective estrogen receptor modulator

SF (1) scatter factor, *see also* **HGF**; (2) splicing factor

SFK Src family kinases

SFRP/sFRP secreted frizzle-related protein (Wnt inhibitor)

SGK1 serum- and glucocorticoid-inducible kinase 1

sgRNA single-guide RNA (in CRISPR-Cas9 procedure)

SH1 Src homology 1 domain (tyrosine kinase domain)

SH2 Src homology 2 domain (phosphotyrosine binding)

SH3 Src homology 3 domain (proline-rich binding)

SHP SH2-containing phosphatase

shRNA small hairpin RNA

SIP1 Smad-interacting protein 1

SIR standardized incidence ratio

siRNA small interfering RNA

Skp2 S-phase kinase-associated protein 2

SKY (multicolor) spectral karyotyping

Sky1 SR-protein–specific kinase of budding yeast

SLE systemic lupus erythematosus

SMA smooth muscle actin

Smac second mitochondria-derived activator of caspase

SMDF sensory and motor neuron-derived factor

Smo Smoothened

SNP single-nucleotide polymorphism

SOD superoxide dismutase

Sos Son of Sevenless

SPP1gene encoding osteopontin

Srf serum response factor

ss single-stranded (DNA or RNA)

STAT signal transducer and activator of transcription

Str-1 stromelysin-1

STS-1 suppressor of T-cell receptor signaling

SUMO small ubiquitin-like modifier

SV simian virus

SWI/SNF mating type switch/sucrose non-fermenting

T (1) thymine; (2) thymidine; (3) threonine

t referring to a chromosomal translocation

$\mathbf{T_{1/2}}$ half-life

T4SS type IV secretion system

$\mathbf{T_{50}}$ 50% of hosts bearing tumors

$\mathbf{T_{mem}}$ memory T cell

$\mathbf{T_{reg}}$ regulatory T cell

TAA tumor-associated antigen

Tag SV40/polyoma T-antigen

T-ALL T-cell acute lymphocytic leukemia

TAM tumor-associated macrophage

TAP transporter associated with antigen processing

TATA tumor-associated transplantation antigen

TAZ transcriptional activator with PDZ-binding motif

$\mathbf{T_C}$ cytotoxic T cell

TCF (1) T-cell factor; (2) T cell-specific transcription factor

TCGA The Cancer Genome Atlas

TCR (1) T-cell receptor; (2) transcription-coupled DNA repair

TdT terminal deoxynucleotidyl transferase

TEAD transcription-enhanced associate domain (transcription factor)

$\mathbf{T_{eff}}$ Effector T cell

TEM transmission electron microscopy

TERRA telomere repeat-containing RNA

TERT telomerase reverse transcriptase

TET ten eleven (chromosomal) translocation

$\mathbf{T_{ex}}$ Exhausted T cell

TF (1) transcription factor; (2) Tissue Factor

$\mathbf{T_{FH}}$ T follicular helper (lymphocyte)

TFSS Type IV secretion system

TGF-α transforming growth factor-α

TGF-β transforming growth factor-β

TGF-βR TGF-β receptor

$\mathbf{T_H}$ helper T cell

thr threonine

TI therapeutic index

TIAM-1 T-cell lymphoma invasion and metastasis-1

TIC tumor-initiating cell (*see also* **CSC**)

TIF telomere dysfunction-induced focus

TIL tumor-infiltrating lymphocyte

TIMP tissue inhibitor of metalloproteinase

TK (1) tyrosine kinase; (2) thymidine kinase

TKI tyrosine kinase inhibitor

TM transmembrane (domain of a protein)

Tm melting temperature

TMB tumor mutational burden

TME *see* **TMEN**

TMEN tumor microenvironment

TNBC triple-negative breast cancer

TNF tumor necrosis factor

TOR target of rapamycin

TORC mTOR-containing complex

TP53 gene encoding p53 TSG

TPA tPA (1) 12-O-tetradecanoylphorbol-13-acetate (*see* PMA); (2) tissue plasminogen activator

TPO thrombopoietin

TRAIL TNF-related apoptosis-inducing ligand

TRAMP transgenic adenocarcinoma of the mouse prostate

TRAP telomeric repeat amplification protocol

Trop-2 human trophoblast cell surface antigen 2

TRF telomeric restriction fragment

tRNA transfer RNA

TrpRS tryptophanyl-tRNA synthetase

ts temperature-sensitive

TSA (1) trichostatin A; (2) tumor-specific antigen

TSC tuberous sclerosis

TSG tumor suppressor gene

TSHR thyroid-stimulating hormone receptor

t-SNE t-distributed stochastic neighborhood embedding (algorithm)

TSP tissue-specific (gene) promoter

Tsp-1 thrombospondin-1

TSS transcription start site

TSTA tumor-specific transplantation antigen

TUNEL TdT-mediated dUTP nick end labeling

tx transformed (cell)

U (1) uracil; (2) uridine

UC ulcerative colitis

UDG uracil-DNA glycosylase

uPA urokinase (type) plasminogen activator

uPAR receptor of uPA

UPR unfolded protein response

UTR untranslated region (of an mRNA)

UV ultraviolet

UV-B ultraviolet-B radiation

V variable region (of an antibody molecule)

VDAC voltage-dependent anion channel

VE vascular endothelial

VEGF vascular endothelial growth factor (=VPF)

VHL von Hippel–Lindau (protein)

VPF vascular permeability factor (=VEGF)

Glossary

3′ UTR The region of an mRNA molecule that is downstream of its reading frame.

5-hydroxymethylcytosine The oxidation product of 5-methylcytosine created by TET enzymes.

5′ UTR The region of an mRNA molecule that is upstream of its reading frame.

abasic Referring to a nucleotide that has lost its purine or pyrimidine base. *See also* **apurinic**; **apyrimidinic**.

abdomen (adj., **abdominal**) Referring to the cavity in vertebrates containing the digestive organs.

ablate To eliminate.

abluminal Located away from the lumen of a duct or other hollow structure.

abscissa Horizontal or *x*-axis of a Cartesian graph. *See also* **ordinate**.

abscission Final step of cytokinesis, when the remaining connections, including those created by microtubules, are severed, allowing complete separation of the two daughter cells. *See also* **cytokinesis.**

acellular Lacking or deprived of cells.

acetylation Covalent attachment of an acetyl group to a second molecule such as a protein.

acetylsalicylic acid Chemical name for aspirin.

acetyltransferase An enzyme that covalently links acetate groups to substrates, such as the amino acid side chains of proteins. *See also* **deacetylase**.

acid test The most rigorous test of an experimental hypothesis.

acinus (pl., **-i**) (1) A hollow saclike structure usually emptying into a duct. (2) A hollow spherical structure formed in culture by certain epithelial cells.

acquired immunodeficiency syndrome Disease caused by infection with human immunodeficiency virus (HIV) that causes depletion of CD4+ lymphocytes and resulting collapse of adaptive immunity.

acquired resistance Referring to the resistance to therapy of a tumor that arises with some delay following and in response to implementation of therapy; *also termed* **secondary resistance**. *See also* **intrinsic resistance**.

acromegaly Pathological condition of excessive growth of certain tissues, notably the hands, feet, and face, usually due to the elaboration of excessive growth hormone by a pituitary tumor.

actin Family of proteins that polymerizes to form microfilaments that help assemble the cytoskeleton of a cell and the thin filaments in contractile structures such as those in muscle.

activation-induced deaminase A cytidine deaminase that introduces point mutations in already-rearranged immunoglobulin genes, preferentially in their V regions, thereby diversifying antigen-binding specificities of the encoded immunoglobulins.

activation loop An oligopeptide loop of a protein kinase molecule that is normally positioned to block access by the catalytic cleft of the kinase to its substrates; phosphorylation of this loop, often by another kinase, causes it to swing out of the way, permitting free access of the catalytic cleft to its substrates.

activator A protein that favors the expression of a gene. *See also* **repressor**.

adaptive immune response An immune system response that is acquired or learned following exposure of an organism to an antigen or antigen-bearing agent. *See also* **innate immune response**.

addiction *See* **oncogene addiction**.

adduct Product of covalently linking a chemically reactive molecule to a targeted substrate molecule, such as the addition of a reactive mutagenic molecule to a base in the DNA.

adenocarcinoma Tumor derived from secretory epithelial cells. *See also* **squamous cell carcinoma**.

adenoma (adj., **-omatous**) Any of a series of premalignant, noninvasive growths in various epithelial tissues, many of which have the potential to progress further to carcinomas. *See also* **polyp**.

adherens junction Lateral cell–cell junction between adjacent cells, notably epithelial cells, that is formed by cadherins displayed on the opposing surfaces of participating pairs of cells; these junctions include the cytoplasmic proteins that are physically associated with the cytoplasmic domains of both participating cadherins and serve to link these junctions, in turn, to the actin cytoskeletons of the two cells.

adipocytes Specialized cells of the mesenchymal lineage, closely related to fibroblasts, that create fat and store it in large globules in the cytoplasm; the dominant cell type in fatty tissues.

adipogenic Causing differentiation into adipocytes.

adjuvant (1) A treatment that is given in concert with or following another treatment. (2) A substance that is given together with an antigen to enhance the immune response. *See also* **neoadjuvant**.

adoptive transfer Procedure in which immune cells are transferred from a donor to a recipient, undertaken with the goal that the donor’s cells will be able to mediate an immune function in the recipient.

adrenal Referring to the hormone-producing secretory glands that sit above the kidneys.

aerobic glycolysis The use by cancer cells of glycolysis as a major source of energy production under aerobic conditions that would normally favor use of the far more efficient Krebs/citric acid cycle; *also termed* **Warburg effect**.

afferent Referring to incoming signals. *See also* **efferent**.

affinity chromatography Procedure for enriching from a complex mixture of biological molecules the subpopulation of biomolecules that binds specifically to a cognate ligand or molecular binding partner, the latter being immobilized on a solid matrix. Molecules that are retained on the matrix, in contrast to the bulk population of molecules that are not, can subsequently be eluted from the matrix and prepared for various additional enrichment or analytic techniques.

age-adjusted Referring to an epidemiologic measurement, such as disease incidence or mortality, that has been adjusted to compensate for the age distribution of the population under study, allowing rates to be compared between populations having different age distributions.

agonist Activating agent; opposite of antagonist.

alkylating Capable of attaching covalently an alkyl group or similarly structured organic chemical group to a substrate such as a DNA base, usually resulting in the replacement of a proton in the substrate with the organic group, thereby forming a covalent bond.

allele One alternative among different versions of a gene that may be defined by the phenotype that it creates, by the protein that it specifies, or by its nucleotide sequence.

allelic deletion Referring to the loss of one of two alternative alleles within a cell and its descendants; such loss can occur via several alternative mechanisms. *See* **allele**, **loss of heterozygosity**.

allogeneic Referring to a pair of tissues or associated cells that differ genetically and, quite possibly, antigenically.

allogeneic stem cell transplantation Clinical procedure involving the transplantation of bone marrow cells from a donor that are genetically and thus antigenically nonidentical with those of a recipient.

allograft Implantation of cells of an animal of one genetic background into a host animal of another genetic background but from the same species.

allograft rejection Process occurring when a donor tissue graft is rejected by the immune system of a recipient because the donor and recipient, although members of the same species, are genetically distinct. *See also* **rejection**.

allosteric Referring to a mechanism for regulating the activity of a protein, notably an enzyme, in which its activity or function is modulated by changes in its three-dimensional structure; the change results from binding of a regulatory molecule at a site within the protein that is distant from the functionally important site, such as, in the case of enzymes, from its catalytic cleft.

alternative splicing Process whereby a pre-mRNA may be spliced in several alternative ways, resulting in mRNAs composed of different combinations of exons.

alternatively activated macrophages *See* **M2 macrophages**.

***Alu* repeat** Sequence block of about 300 bp that is found in almost 1 million copies scattered throughout the human genome.

alveolus (pl., **alveoli)** A small sac within a tissue that is connected to a duct, such as the sacs seen in the lung and in the mammary gland during pregnancy.

ambient Referring to conditions in the immediate surroundings.

Ames test An experimental protocol and versions thereof that enable the quantification of the mutagenic potency of candidate chemicals through their ability to induce mutations in bacteria growing in a Petri dish.

amino Referring to the end of an oligopeptide or protein chain that is formed first. *See also* **carboxy**.

amoeboid Exhibiting the shape and motility reminiscent of the behavior of the amoeba protozoan.

amphipathic Describing a molecule containing distinct hydrophobic and hydrophilic domains.

AMPK Kinase regulator of autophagy that responds to low intracellular ATP levels by negatively regulating components of the mTOR complex while stimulating certain enzymes that contribute to ATP production and others that decrease ATP consumption.

amplicon A defined stretch of (chromosomal) DNA that undergoes amplification flanked on both sides by DNA segments that are present in normal copy number.

amplification Genetic mechanism by which the copy number of a gene is increased above its normal level in the diploid genome.

anabolism (adj., **anabolic**) Processes by which new biological molecules are assembled via biosynthetic reactions. *See also* **catabolism**.

analogous Referring to two genes or proteins that have similar functions whether or not they share common evolutionary descent. *See also* **homologous**.

anaphase Third subphase of mitosis, during which the paired chromatids are segregated to the two opposite poles of the cell.

anaphase bridge A connection between two clusters of chromosomes that forms during anaphase and results from the simultaneous association of an

individual chromatid with both chromosomal clusters and their respective sets of spindles. *See also* **spindle**.

anaplastic (Referring to a tumor) having a tissue and cellular architecture lacking the differentiated characteristics of an identifiable tissue-of-origin or tumor type.

anastomosis End-to-end connection formed between two ductal structures, such as a connection formed directly between an artery and a vein.

anchorage dependence Requirement of cells for tethering to a solid substrate before they will grow.

anchorage independence Ability of a cell to proliferate without attachment to a solid substrate.

androgen Steroid hormone that stimulates development of male characteristics.

aneuploid (1) Describing a karyotype that deviates from diploid because of increases or decreases in the numbers of certain chromosomes. (2) Less commonly, describing a karyotype that carries structurally abnormal chromosomes.

angiogenesis Process by which new blood vessels are formed by sprouting from existing vessels; *also called* **neoangiogenesis** in certain circumstances. *Compare* **vasculogenesis**.

angiogenic factor Type of secreted growth factor that is specialized to induce angiogenesis.

angiogenic switch Shift by a mass of tumor cells from a state in which they are unable to induce neovascularization to one in which they exhibit this ability.

angiosarcoma Tumor of the cells that are precursors to endothelial cells.

annexin V A cellular protein that has strong affinity for binding of phosphatidylserine (PS); binding of this protein to the surface of intact cells

indicates that the usual segregation of PS to the inner leaflet of the bilayered plasma membrane has been disrupted, as occurs during apoptosis and other forms of cell death.

anoikis Form of apoptosis that is triggered by the failure of a cell to establish anchorage to a solid substrate, such as the extracellular matrix, or by loss of such anchorage.

anonymous (marker) Referring to a segment of genomic DNA that is not affiliated with any known gene or biological function.

anoxia State or environment in which oxygen is essentially absent.

antagonist Agent acting against another agent or process of interest. *See also* **agonist**.

antibody A soluble tetrameric protein that is produced by plasma cells of the immune system and is capable of recognizing and binding particular antigens with high specificity. *See also* **immunoglobulin**.

antibody-dependent cellular cytotoxicity A form of attack by cytotoxic immune cells, such as NK cells, that depends on the presence of antibody molecules bound to antigens displayed on the surface of the targeted cells.

antibody-mediated cellular phagocytosis Attack on targeted cells by phagocytic cells, such as macrophages, that is triggered by antibody molecules bound to antigens displayed on the surface of the targeted cells.

antigen (adj., **-genic**) Molecule or portion of a molecule, often an oligopeptide, that can be specifically recognized and bound by an antibody or a T-cell receptor or that provokes the production of an antibody. *See also* **immunogenic**.

antigen-presenting cells A class of cells—often termed professional antigen-presenting cells, including dendritic cells, macrophages, and B cells—that present oligopeptide antigens via class I and II MHC molecules to other immunocytes, notably helper and cytotoxic T cells.

antimetabolite Compound, typically used as an anti-tumor cytotoxic drug, that acts through its ability to interfere with the synthesis or function of a normal cellular metabolite.

antisense RNA RNA molecules that, following introduction into or expression within cells, are capable of inhibiting the functions of targeted RNA molecules in those cells because the introduced RNAs have sequences complementary to those of the targeted RNAs and presumably form dsRNA molecules with them.

antiserum Serum that is produced by an animal exposed to a specific antigen or agent and contains antibodies that are able to recognize and bind that antigen or agent.

apatite Mineral component of bone composed of calcium phosphate crystals.

apex (adj., **apical**) Uppermost point of an object or collection of objects. *See also* **basal**.

apheresis Procedure involving the drawing of blood from a patient, the fractionation of the blood into plasma and various cellular components, the removal and purification of certain cellular components of the blood such as specific types of leukocytes, and the reintroduction of the remaining blood components into the patient's circulation. *See also* **leukapheresis.**

apical Referring to the surface of an epithelial cell that is facing an exposed surface of the epithelium such as its luminal surface.

apico–basal polarity Referring to the asymmetric organization of epithelial cells, often termed polarization, in which many proteins and subcellular structures, notably cytoplasmic and cell surface molecules, are preferentially localized toward either the apical surface (facing a lumen) or the basal surface (facing a basement membrane). *See* **polarity**.

APOBEC A class of cellular enzymes that mutate genomic sequences by deaminating genomic cytidine residues, thereby converting them into uridine residues, leading to C-to-T mutations.

apoptosis Complex program of cellular self-destruction, triggered by a variety of stimuli and involving the activation of caspase enzymes, which drive rapid fragmentation of diverse cellular structures and elimination of all breakdown products of a cell and phagocytosis of resulting cell fragments by neighboring cells or macrophages. *See also* **ferroptosis**, **necroptosis**, **pyroptosis**.

apoptosome Multiprotein complex that consists of cytochrome *c* molecules and Apaf-1 and helps to initiate apoptosis by activating procaspase 9 into caspase 9. *See also* **caspase**.

apposed Physical entity located directly adjacent to a second one.

apposition Referring to the close physical positioning of one entity with another, such as one cell with another.

apurinic Referring to the product of depurination, in which the glycosidic bond linking a deoxyribose or ribose to a purine base is broken, leaving behind only the deoxyribose or ribose in the DNA or RNA, respectively. *See also* **depurination**.

apyrimidinic Referring to the product of depyrimidination, in which the glycosidic bond linking a deoxyribose or ribose to a pyrimidine base is broken, leaving behind only the deoxyribose or ribose in the DNA or RNA, respectively. *See also* **depyrimidination**.

aromatic Referring to an organic molecule that contains one or more benzene rings.

arrestin A protein involved in inhibiting or redirecting downstream signals of ligand-activated GPCRs.

arteriole A small artery that empties into capillaries.

artifact (adj., **artifactual**) A misleading observation or finding that results from the conditions or design of an experiment rather than from an intrinsic property of the entity being studied.

ascertainment bias Tendency of some conclusions or measurements to be strongly influenced by the observational tools that are used to generate them, including the ease or difficulty of applying such tools to a specific biological situation.

ascites (adj., **-itic**) Fluid that accumulates in the peritoneal cavity of some cancer patients, often containing malignant cells.

astrocytoma A glioma tumor deriving from astrocytes. *See* **glioma**.

asymmetric division Process whereby a mother cell, notably a stem cell, generates two daughters that reside in distinct states of differentiation; usually one daughter retains the phenotype of the mother cell while the second daughter acquires novel phenotypes or launches a program of differentiation. *See also* **self-renewal**, **symmetric division**, **stem cell**.

asynchronous Referring to a population of cells that are dispersed throughout the cell cycle during any point of time and therefore do not execute specific cell-cycle steps in a coordinated or synchronous manner.

ATAC-seq Procedure for mapping open chromatin by determining stretches of genomic DNA that are accessible for modification by the Tn5 transposase.

ataxia Loss of muscle coordination, often caused by cerebellar dysfunction.

atelomeric Lacking a telomere.

atrophy Shrinkage of a tissue, often caused by loss of viability of its component cells and resulting loss of normal cell numbers.

atypia Histopathological term for an abnormally appearing cell or collection of such cells.

autochthonous (1) Of native origin. (2) Referring to a tumor that arises within an organism (rather than from implanted cells or tumor fragments).

autocrine Referring to the signaling path of a hormone or factor that is released by a cell and proceeds to act upon the same cell (or same cell type)

that has released it. *Compare* **endocrine**, **exocrine**, **intracrine**, **juxtacrine**, **paracrine**.

autoimmune Referring to a process or disease in which the immune system attacks an organism's own normal cells and tissues. *See also* **autoreactive**.

autologous Referring to biological material, usually cells or tissues, that originates in a patient's own body (and may be reintroduced into that patient following some manipulation *ex vivo*).

autophagic cell death A form of cell death associated with autophagy in which dying cells sequester large portions of their cytoplasmic contents in autophagosomes. This form of cell death lacks the characteristic chromatin condensation seen in apoptosis. *See* **autophagosome, autophagy**.

autophagosome The specialized intracellular vesicle that is formed during the course of autophagy and encloses cytoplasmic organelles and other cellular products prior to fusion with lysosomes. *See also* **autophagy**.

autophagy A catabolic process whereby selected intracellular organelles and molecules are degraded by engulfment in autophagosomes that proceed to fuse with lysosomes in which degradation occurs, yielding metabolites that can be recycled for biosynthetic reactions.

autophosphorylation Phosphorylation of a protein molecule by its own associated kinase activity. *See also* **transphosphorylation**.

autoradiography Procedure for detecting radiolabeled molecules by placing them (or the samples carrying them) adjacent to a radiographic emulsion, which responds to radioactive decay by producing silver granules. *Also termed* **radioautography**.

autoreactive Referring to the ability of components of the adaptive immune system—including antibody molecules and lymphocytes—to recognize and react with antigens displayed by normal tissues, resulting in autoimmunity. *See also* **autoimmune**.

autosome A chromosome that is not a sex chromosome, i.e., neither an X nor a Y chromosome.

avidity Referring to the strength with which one molecule binds another, such as the interaction of an antibody molecule binding its cognate antigen(s).

axillary Referring to the armpit.

axon Long slender protrusion from the cell body of a neuron through which nerve signals are transmitted, often to other neurons.

B-cell receptor An immunoglobulin molecule that is displayed on the surface of a B cell that enables this cell to recognize and respond to specific antigens.

B cells Lymphocytes, also termed B lymphocytes, that develop in the bone marrow and are involved in generating the humoral immune response. *See also* **T cells**.

bacteriophage Virus that infects bacteria.

barcode Distinct labels, usually in the form of specific oligonucleotide DNA sequences, that are introduced into the individual cells within a cell population and used subsequently to identify each of these cells and their lineal descendants; the DNA sequences within a barcode library often represent randomly generated oligonucleotide sequences.

Barr body The condensed, inactive X chromosome found in each of the cells of females of placental mammals.

Barrett's esophagus Metaplasia in which squamous epithelium of the esophagus is replaced by secretory epithelial cells of a type normally found in the stomach. *See also* **metaplasia**.

basal (1) Referring to a lower physical location. (2) Referring to cells in an epithelium that are located away from an exposed surface of the epithelium such as its luminal surface. (3) Referring to the surface of an individual

epithelial cell that is located away from an exposed surface of the epithelium such as its luminal surface. (4) Referring to a (low) rate of activity or function observed in the absence of any activating stimulus. *See also* **apical**.

basal lamina *See* **basement membrane**.

basaloid Having the characteristics of a basal epithelial cell. *See also* **basal**.

base-excision repair A form of DNA repair that initially involves cleavage by a repair enzyme of the glycosidic bond between a base and a deoxyribose, leaving behind an abasic nucleotide. *Compare* **nucleotide-excision repair**.

basement membrane The specialized extracellular matrix that forms a sheet separating epithelial from stromal cells or endothelial cells from pericytes. *Also termed* **basal lamina**.

basophilic Referring to entities in a histopathological section, such as cell nuclei, that are stained preferentially by basic dyes such as hematoxylin.

benign (1) Describing a growth that is confined to a specific site within a tissue and gives no evidence of invading adjacent tissue. (2) Referring to an epithelial growth that has not penetrated through the basement membrane.

biallelic Referring to a state in which both copies of a gene are expressed or exert effects on phenotype. *See also* **monoallelic**.

bioavailability Proportion or amount of a substance that is available for absorption into cells and tissues or is able to exert biological effects on the cells of those tissues.

bioinformatics Science of using computational methods for analyzing biological information, notably complex sets of biological data.

biomarker A measurable property or parameter of a cell, tissue, or organism that provides information about the biological state of the entity

being analyzed; biomarkers can be used for stratification of disease subtypes and, in the clinic, for disease diagnosis or prognosis.

biopsy Retrieval of a sample of living tissue performed in order to understand the properties of the tissue using various analytical procedures.

biosynthesis Process by which new biological molecules are synthesized from precursor substrates via various biochemical reactions.

biotinylation Process of covalently attaching a biotin molecule to a protein or nucleic acid.

bispecific Able to specifically recognize or bind two objects simultaneously.

bispecific T-cell engager A re-engineered antibody-derived molecule that simultaneously binds a T cell displaying a T cell-specific cell surface antigen, often CD3, to a second cell, such as a targeted cancer cell that displays a distinct cell surface antigen; such an antibody is used to drive the physical linking and thus juxtaposition of the T cell with the targeted cell.

bisphosphonates Class of drugs, characterized by a chemical backbone with the structure P–C–P, that are incorporated into bone apatite and subsequently become available to poison osteoclasts that may later undertake to dissolve the bone, thereby liberating the previously incorporated toxic bisphosphonates.

bistable Referring to a control device or a system that resides stably in either one of two alternative states.

blast Term used as prefix or suffix, indicating a relatively undifferentiated or embryonic precursor cell.

blast crisis Clinical state occurring when a hematopoietic tumor that has been under therapeutic control relapses into a highly aggressive stage of disease progression in which the erupting tumor cells are in a primitive state of differentiation. *See* **blast**.

blastocoel Inner cavity present in a blastocyst.

blastocyst An early stage of vertebrate embryogenesis in which the embryo consists largely of an outer layer of cells enclosing an inner cavity that contains a cell mass destined to form the embryo.

bleb A small, bubble-like herniation through a membrane such as the plasma membrane.

blood–brain barrier The barrier created by specialized endothelial cells and basement membrane that operates, together with astrocytes, to prevent transport of solutes between the blood and the parenchyma of the brain.

body-mass index Anatomical metric calculated by dividing the weight of the body (measured in kilograms) divided by the square of height in meters.

bona fide Genuine, authentic.

Boyden chamber A cylindrical two-chambered plastic vessel in which the upper and lower chambers are separated by a membrane whose porosity allows molecules or, alternatively, whole cells to pass between them.

brachytherapy Form of radiotherapy in which a radioactive source carried within a small capsule or vessel is implanted in a patient’s tissue in order to generate localized high-intensity irradiation.

breakpoint Location in a chromosomal region or gene at which it becomes fused through chromosomal translocation with another chromosomal region or gene.

bronchial Referring to a major airway of the lung.

bronchoalveolar Subtype of lung adenocarcinoma usually arising in peripheral areas of the lung and referring to tissues derived from small airways termed bronchioles and associated alveoli. *See also* **alveolus**.

bronchoscope A flexible tube that can be inserted into the major air passages of the lungs and allows visual surveillance of the walls of these passages.

buccal Referring to the tissues of the oral cavity, specifically the epithelial lining of the cheek.

bypass polymerase A DNA polymerase that will copy over an unrepaired lesion in the template strand of the DNA, “guessing” (often in an error-prone fashion) the nucleotides that should be incorporated into the nascent complementary DNA strand in order to avoid undesirable stalling of replication forks.

bystander effect Mechanism through which normal cells or tissues near to those directly targeted are also affected.

bystander mutation *See* **passenger mutation**.

C-terminus (adj., **-al**) End of a protein chain that is synthesized last. *See also* **N-terminus**.

cachexia Physiological state, often seen late in cancer development, in which the patient loses appetite and suffers wasting of tissues throughout the body.

café au lait spots Coffee-with-milk–colored spots on the skin that are seen characteristically in patients suffering the neurofibromatosis type 1 syndrome.

calreticulin A cell surface protein whose display by a cell incites the phagocytosis of the cell by macrophages.

canaries in the mine Referring to the use of a highly sensitive sentinel to detect and report an early warning.

cancer (1) A clinical condition that is manifested by the presence of one or another type of neoplastic growth. (2) A malignant tumor.

Cancer Dependency Map The product of an effort focused on systematically cataloging the key roles of genes throughout the entire human genome whose inactivation by CRISPR/Cas9 leads to the death of cells belonging to specific cancer cell lines.

cancer of unknown primary A tumor, often a metastasis, whose histopathological appearance does not permit a determination of its tissue-of-origin within a patient. *See also* **primary tumor**.

cancer stem cell A neoplastic cell that resides within a tumor, is able to both self-renew and generate non-stem-cell progeny, and can be defined experimentally by its ability to seed a tumor when implanted in a suitable host such as a mouse. *Also termed* **tumor-initiating cell**.

canonical Referring to the most widely accepted representation of an entity or process, often the one that is initially discovered and characterized. *See also* **non-canonical**.

capsid Protein coat of a virus particle that envelops and protects the viral genome.

carboxy (1) Referring to the end of an oligopeptide or protein chain that is completed last. (2) Referring to the ionizable group of an organic acid. *See also* **amino**.

carcinogen An agent that contributes to the formation of a tumor.

carcinogenic Capable of causing or contributing to the causation of cancer.

carcinoma (adj., **-omatous**) A cancer arising from epithelial cells.

cardia Region of the stomach adjacent to its junction with the esophagus.

caretaker A gene that encodes a protein that maintains the integrity of the genome and thereby prevents the accumulation of mutations and, in turn, the formation of neoplastic cells. *See also* **gatekeeper**.

cascade model (of metastasis) A hypothetical model that posits that initially formed metastatic colonies rather than corresponding primary tumors are the sources of a secondary wave of metastatic dissemination and thus metastatic colonies.

caspase A protease that contains cysteine in its catalytic site and cleaves substrate proteins after aspartic acid residues. *See also* **apoptosome**.

CAT scan A clinical procedure in which multiple successive two-dimensional sections of a patient's body or specific tissue are imaged by X-rays and integrated with one another using informatics in order to provide a three-dimensional survey of an extensive portion of a patient's body or tissue.

catabolism (adj., **catabolic**) Metabolic process involving the breakdown of biological molecules, often used to generate energy or the precursors of new molecules. *See also* **anabolism**.

catalase An enzyme that catalyzes the reaction by which hydrogen peroxide is decomposed to water and oxygen.

catalytic cleft Region of a protein, usually an accessible cavity, in which enzymatic catalysis is accomplished by this protein.

CD3 Antigen representing a protein complex associated with the T-cell receptor and used to identify T cells and a subset of NK cells.

CD4 Cell surface protein displayed by helper T cells that enables them to recognize MHC-II proteins on the surface of professional antigen-presenting cells.

CD8 Cell surface protein displayed by cytotoxic T cells that enables them to recognize MHC-I proteins on the surface of cells that they may thereafter target for destruction.

CD20 Antigen that is displayed on the surface of multiple cell types of the B-cell lineage.

CD45 The common leukocyte antigen expressed by all cells of the hematopoietic lineage except platelets and erythrocytes.

CD47 Cell surface protein displayed by various cell types that discourages attack and phagocytosis by macrophages.

CD antigens Cell surface antigens that were initially characterized in human leukocytes in order to determine their immunophenotypes and later

determined for non-leukocyte cell types as well; by 2016, 371 distinct human CD antigens and comparable number of mouse CD antigens had been identified.

celecoxib A clinically employed nonsteroidal anti-inflammatory drug that strongly inhibits the COX-2 enzyme.

cell-autonomous Referring to a trait or behavior of a cell that is governed by its own genome and internal physiology and not by its ongoing interactions with other cells and its tissue microenvironment.

cell culture Procedure for propagating cells in various types of vessels using chemically defined media, usually with admixed serum.

cell cycle The sequence of changes in a cell from the moment when it is created by cell division, continuing through a period in which its contents including chromosomal DNA are doubled, and ending with the subsequent cell division and formation of two daughter cells.

cell cycle clock Network of signaling proteins in the nucleus that regulate and orchestrate progression of the cell through its growth-and-division cycle. *See also* **cell cycle**.

cell fate The entrance of a less-differentiated cell into a specific differentiation lineage and eventual differentiated state, often determined by a cell long before such a cell manifests specific markers of such a state.

cell-heritable Trait that is transmitted from a mother cell to one or both of its daughters; such heritability may result from genetic mutation or nongenetic mechanisms.

cell line Strain of cells that has been adapted for indefinite propagation in culture.

cell-of-origin The fully normal cell that serves as the ancestor of all the neoplastic cells within a tumor, i.e., their last common normal ancestor.

cellular immune response The arm of the immune system that depends on the ability of specific cell types, such as B cells, cytotoxic T cells, natural killer cells, and macrophages, to recognize and respond to specific entities or agents, notably those expressing certain antigens; such recognition may be followed by the immune cell-mediated destruction of the recognized entities, including abnormal cells and infectious agents. *See also* **humoral immune response**.

cellularity The proportion of the volume of a tumor that is represented by living cells rather than extracellular matrix and cellular debris.

central tolerance Process by which immature T-cells recognizing self-antigens are eliminated in the thymus. *Compare* **peripheral tolerance**.

centriole Component of a centrosome from which spindle fibers radiate during mitosis and meiosis.

centromere Region of a chromosome that holds the two chromatids together and that binds, via a kinetochore, with mitotic or meiotic spindle fibers.

centrosome A body in the cytoplasm containing a pair of centrioles, ancillary proteins, and outward radiating microtubules that functions to organize one-half of a mitotic spindle. *See also* **centriole**, **spindle**.

chain-terminating nucleotide A nucleotide that lacks a 3′-OH group, which is required for the formation of a phosphodiester bond between two nucleotides. The insertion of a chain-terminating nucleotide causes DNA polymerase to cease extension due to the inability to form a new phosphodiester bond with an incoming nucleotide.

chaperone *See* **molecular chaperone**.

checkpoint (1) Control mechanism that ensures that the next step in a process does not proceed until a series of prerequisites and conditions have been fulfilled. Such prerequisites may include, as examples, the successful completion of all previous steps during cell-cycle progression or the integrity of the cell genome. (2) Control mechanism that limits or constrains

the immune-mediated attack on targeted cells. *See also* **immune checkpoint**.

chemokine (1) A polypeptide that serves as an attractant for motile cells, notably leukocytes, via chemotaxis. (2) More narrowly, a member of a family of low–molecular-weight (8–10 kD) secreted proteins, most of which contain four cysteine residues in evolutionarily conserved sites. *See also* **chemotaxis**.

chemo-refractory Resistant or unresponsive to treatment by chemotherapy.

chemotaxis (adj., **-tactic**) Movement of a cell toward high concentrations of a soluble attractant such as a chemokine or growth factor. *See also* **chemokine**, **haptotaxis**.

chemotherapy Use of introduced low–molecular-weight drugs to treat a cancer, often because they have cytotoxic effects on proliferating cancer cells.

chimera Organism or molecule in which different parts or tissues derive from genetically distinct parents or genetically distinct origins.

chimeric antibody *See* **chimerized**.

chimeric antigen receptor Cell surface antigen-binding receptor generated by recombinant DNA in which antigen-binding and transmembrane domains have been fused with segments of intracellular signal-emitting domains, resulting in strong potentiation of antigen-provoked signaling within a T cell.

chimerization Process whereby a donor cell introduced into a host embryo —usually of a different genotype—is able to insert itself into that embryo and participate in the formation of some of the subsequently formed tissues arising from that embryo.

chimerized (1) Referring to the protein product of a re-engineered gene in which two portions of the protein derive from two distinct sources, such as two distinct species. (2) Describing an antibody molecule whose constant

(C) region amino acid sequences have been replaced by the homologous sequences from another species, e.g., one in which a mouse C region is replaced by a human C region.

ChIP-seq Procedure for determining chromosomal DNA sequences that are bound to specific proteins by immunoprecipitating the proteins of interest together with bound DNA followed by sequencing of co-precipitated DNA.

cholangiocarcinoma Tumor of the bile ducts in the liver, sometimes termed cholangiosarcoma.

chromatid A half chromosome that exists after S phase and before M phase; paired chromatids are separated at M phase, whereupon each becomes a chromosome.

chromatin Complex of DNA, RNA, and protein molecules that together constitute chromosomes.

chromogenic A chemical that generates a visible pigment upon enzymatic alteration; *sometimes called* **chromagenic**.

chromophore A chemical entity that serves to emit light, usually colored light visible via microscopy.

chromothripsis The presence of multiple chromosomal rearrangements usually limited to a single chromosomal region and suggesting the involvement of an initial catastrophic shattering of a chromosomal domain followed by rejoining of the fragmented segments in random order and orientation. *See also* **kataegis**.

chronic myelogenous leukemia An excess of the cells originating in the bone marrow that are precursors of granulocytes; these cells accumulate in large numbers in the blood of patients. *See also* **granulocyte**.

chymotryptic Referring to proteolytic reaction similar to that of chymotrypsin that cleaves protein substrates adjacent to hydrophobic amino acids.

cilium (pl., **cilia**) A cellular organelle that protrudes from the surface of a eukaryotic cell, is wrapped by a lipid bilayer, and contains in its core a unique arrangement of cytoskeletal proteins; a cilium may either be motile or non-motile. *See also* **primary cilium**.

circos plot Graphic convention in which the chromosomes of a cell, usually of human origin, are plotted in a circular array (often arrayed by increasing chromosome number ranging from Chromosomes 1 to 22 plus X and Y), in which translocations are indicated as arcs connecting participating chromosomal regions, and in which localized changes in copy number, chromosome structure, and mutational status are indicated in concentric outer circles.

circulating tumor cell A neoplastic cell that has entered into the general circulation following intravasation and dwells in the circulation for a brief period of time before being trapped in microvessels or eliminated by components of the immune system.

cis (1) Referring to an effect on a genetic segment exerted by the actions of a physically linked genetic segment. (2) Referring to a structural configuration of a molecule, often a complex organic molecule, in which two moieties are oriented in the same direction or on the same side of a plane. *See also* **trans**.

cistrome The entire set of targeted genes present in a genome that are acted upon by (a trans-acting) transcription factor. *See* **trans-acting**.

citric acid cycle *See* **tricarboxylic acid cycle**.

class switching Gene rearrangement occurring in an immunoglobulin gene locus in which an already-formed antigen-binding variable region-encoding sequence is switched from its juxtaposition with one constant region-encoding segment to another constant region-encoding segment; such switching enables one variable region of an immunoglobulin to be expressed in a number of alternative classes of immunoglobulins and related receptors.

clinical presentation *See* **presentation**.

clonal expansion Process by which a cell that has acquired a more advantageous phenotype generates a large population of lineal descendant cells, which in aggregate constitute a clone; such clonal populations may be generated during the process of tumor progression or in lymphocytes that are stimulated to proliferate by encounter with an antigen that is cognate with the cell surface receptor that they display.

clonal hematopoiesis Development in hematopoietic cell lineages of clonal populations of cells in which the constituent cells share a common somatic mutation or set of mutations that appears to favor their preferential clonal expansion in the hematopoietic system; such cells have nonetheless not developed a frankly neoplastic phenotype although they may be poised to do so.

clonal succession Process by which one clonal population of cells displaces and thus succeeds a preexisting clonal population of cells; by implication, the displacing cell population has acquired a more advantageous phenotype relative to that of the cell population that is being displaced. *See also* **clonal expansion**.

clonality Condition describing the state of a population of cells, all of which descend from a common progenitor. The cells within this population share a common genetic or epigenetic alteration inherited from this progenitor.

clone (adj., **clonal**) (1) Copy of a gene that has been isolated by recombinant DNA procedures and amplified into a large number of identical copies. (2) Population of cells, all of which descend from a common progenitor cell. (3) Offspring of a procedure of asexual reproduction in which the genome of a somatic diploid cell of an organism is used to form a cell that functions equivalently to a fertilized egg that may itself develop thereafter into an entire organism.

co-activator Protein that associates with a DNA-binding transcription factor and causes, directly or indirectly, the modification of nearby chromatin proteins and a resulting stimulatory effect on the transcription of an adjacent gene. *See also* **co-repressor**.

co-carcinogen An agent or substance that, while not carcinogenic on its own, collaborates with another agent to enable carcinogenesis to proceed.

cognate Corresponding to or related to.

co-inhibitory (1) Referring to a molecule or process that operates in concert with a major inhibitory process to ensure completion of the latter or to amplify its effects. (2) Receptor that, when displayed in conjunction with a T-cell receptor, will dampen the duration of subsequent T-cell activation; such a receptor will recognize a ligand presented by a potential target cell. *See also* **co-stimulatory**.

cold tumor A tumor that lacks evidence of extensive immune cell infiltration and inflammation.

collective invasion Process whereby a cohesive mass of invasive cancer cells invades in a coordinated fashion into nearby tissue.

collective metastasis Process whereby a cluster of circulating tumor cells function as the founders of a metastatic colony, yielding a polyclonal growth formed by the lineal descendants of the multiple clustered disseminating tumor cells.

colonization Proliferation of cells within a micrometastasis that leads to the formation of a macroscopic metastasis.

colonoscopy Clinical procedure used to visually survey the wall of the colon via insertion of an optical tube through the rectum, employed used to detect previously undiagnosed polyps.

colony (1) Cluster of cells, usually of clonal origin. (2) Cluster of cells that is able to proliferate in the absence of anchorage to a solid substrate.

colorectal Referring to the lower gastrointestinal tract including the colon and rectum.

commensal Referring to a long-term interaction between two organisms, such as gastrointestinal bacteria and their mammalian hosts, which reflects

symbiosis between the organisms and may accrue to the benefit of both of them.

commitment Decision made by a relatively undifferentiated cell to enter into one or another differentiation lineage and generate a limited repertoire of descendant differentiated cell types.

committed progenitor Less differentiated progenitor cell that is committed to spawning a population of descendant cells that are able to differentiate into a limited repertoire of distinct cell types. *See also* **progenitor cell**.

comparative genomic hybridization Procedure in which the copy numbers of a large array of genomic sequences from cells of interest are compared with the copy numbers of the corresponding sequences in normal reference DNA in order to determine whether the various sequences being analyzed are present in the cells of interest in increased or decreased copy number.

compartment Physical or virtual functional space that contains all cells of a given type within a tissue, e.g., a stem cell compartment.

competitive inhibition Mechanism whereby an inhibitory molecule reduces enzyme function by binding to the same site in the enzyme that is bound by the usual substrate of this enzyme.

complement Group of collaborating plasma proteins that can associate with antibody molecules bound to cell surface antigens, such as antigens displayed by bacterial, yeast, or mammalian cells; once attached via these antibody molecules to a cell surface, complement can kill the cell by introducing pores into the nearby cell membrane, including the plasma membrane of mammalian cells.

complementarity-determining region The variable domains of the heavy and of the light chains of antibody molecules and of the T-cell receptors that recognize and bind antigens; each of these regions is formed from three oligopeptide loops, meaning that, as an example, an antibody molecule possesses altogether six such loops in each of its two antigen-binding domains.

complementarity State in which two nucleic acid molecules can anneal to one another via hydrogen bonding because their respective base sequences are complementary with one another.

complementary DNA DNA strand that is produced on an RNA template by reverse transcriptase.

complementation Ability of two mutant genotypes, when coexisting in the same cell or organism, to compensate for each other's defects and thereby create a wild-type phenotype, indicating that the two genotypes carry changes in distinct genes and therefore can be classified as belonging to distinct complementation groups. *See also* **complementation groups**.

complementation group A set of genes or alleles, all of which behave identically when tested for their ability to complement the genetic defects present in a set of mutant organisms or cells. *See also* **complementation**.

complete carcinogen An agent that can act as both an initiator and a promoter of tumor progression. *See* **initiation, promotion**.

complete response Elimination of all detectable neoplastic tissue following an anti-cancer therapy. *See also* **partial response**.

computed tomography Procedure in which imaging generated by successive X-ray scans of sections of a tissue or of the entire body is processed digitally to generate a three-dimensional image of the tissue or of the entire body, sometimes termed computed axial tomography.

concatemer (1) A molecule resulting from end-to-end joining of multiple copies of a molecular species, such as a DNA sequence or a viral DNA genome. (2) DNA molecules that are topologically intertwined in a fashion that can only be resolved by the actions of a topoisomerase. *See also* **topoisomerase**.

conditional Referring to a phenotypic state or genetic change that only occurs under certain conditions, often in response to physiological signals or those induced experimentally. *See also* **constitutive**.

conditioned medium Culture medium that arises after cells have been propagated *in vitro* for a period of time; the secretion of various factors into the medium by these cells then imparts to this medium biological or biochemical properties.

confluence State reached when cells in monolayer culture proliferate until they fill available space at the bottom surface of a Petri dish.

congenic Referring to a genotype that differs from another only by the presence of a single or a small number of identified alleles.

congenital Referring to a condition that is already present at birth and may persist thereafter.

constant region Portion of an antibody molecule that is present identically by all members of a class of these molecules, e.g., all immunoglobulin gamma molecules. *Compare* **variable region**.

constitutive Describing a state of activity that occurs at a constant level and is therefore not responsive to modulation by physiologic regulators, or a type of control that yields such a constant output. *See also* **conditional**.

constitutive heterochromatin Regions of chromosomes that are permanently in a heterochromatic and thus transcriptionally inactive state, in contrast to facultative heterochromatin, which may become euchromatic in response to developmental or physiological signals. *See also* **facultative heterochromatin, euchromatin**.

constitutive proteasome Term used to describe the proteasome that is present in a wide variety of cell types and is responsible for the degradation of most cellular proteins; this class of proteasomes is distinguished from immunoproteasomes that degrade intracellular proteins in order to generate the oligopeptides that are loaded onto Class I MHC/HLA proteins and presented on the cell surface. *See also* **proteasome**, **immunoproteasome**.

contact inhibition Behavior exhibited by cells propagated in monolayer culture, reflecting the halt in cell proliferation when adjacent cells touch one another. *Also termed* **density inhibition**.

contralateral Referring to the opposite side of the body of a bilaterally symmetrical organism.

convergent evolution The independent development by multiple species of a common trait during the course of evolution.

copy choice Genetic recombination mechanism whereby, during the replication of DNA on one chromosome, the replication machinery switches to using the DNA sequences on another chromosome as template.

copy number variation Alteration involving the number of copies of a gene or chromosomal region present in a genome, usually the genome of a neoplastic cell that has undergone somatic mutation.

co-receptor Cell surface protein that is displayed in conjunction with a nearby receptor and modulates the function of the latter by modulating its ligand specificity or signaling powers.

co-repressor Protein that associates with a DNA-binding transcription factor and causes, directly or indirectly, the modification of nearby chromatin proteins and a resulting inhibitory effect on the transcription of an adjacent gene. *See also* **co-activator**.

cortex (adj., **cortical**) The region of the cytoplasm that immediately underlies the plasma membrane. *See also* **cortical actin**.

cortical actin Referring to the outer layer of actin filaments that lie just below and in a plane parallel with that of the nearby plasma membrane. *See also* **cortex**.

co-stimulatory (1) Referring to molecules or processes that operate in concert with a major stimulatory process to ensure completion of the latter or to amplify its effects. (2) Referring to a receptor that, when acting in concert with a T-cell receptor, can act to stimulate the resulting T-cell response; such a receptor will recognize a ligand displayed by a potential target cell. *See also* **co-inhibitory**.

co-translational Process occurring during the course of and coordinated with translation.

counterstain Histological procedure in which the microscopic entity of interest is viewed in the context of or is contrasted with other entities by staining the latter with a different dye or other substance.

CpG island Cluster of CpG dinucleotide sequences located in the vicinity of a gene promoter; the increased methylation of these CpGs may lead to transcriptional repression of the nearby gene. *See also* ***de novo* methyltransferase**.

Cre A bacterial recombinase enzyme that catalyzes the site-specific recombination between two loxP sites, resulting in the excision of the DNA sequences between them. *See* **loxP**.

crisis (1) Cellular state arising when cells lose telomeres of a length that is required to protect the ends of chromosomal DNA, resulting in the end-to-end fusion of chromosomes, karyotypic chaos, and widespread cell death by apoptosis. (2) Clinical state when patients whose tumors have been under therapeutic control relapse into a highly aggressive phase of disease.

CRISPR/Cas9 A genetic procedure in which a targeted gene within a cell is altered with specificity and accuracy achieved by associated sequence-specific guide RNAs and a specialized nuclease. *See also* **knock-out**, **knock-in**.

cross-immunity Immunity that has initially arisen against a particular antigen or infectious agent that is subsequently found to confer immunity against another distinct antigen or infectious agent.

cross-presentation The presentation by antigen-acquiring cells, notably dendritic cells, of peptides acquired from other cells and cellular debris on the MHC-I cell surface molecules of the antigen-acquiring cells; such presentation occurs concomitantly with peptide presentation by these cells via their MHC-II molecules.

cross-reactive Referring to the ability of an antibody to recognize and/or bind antigens other than the antigen of interest.

cruciferous Referring to a closely related group of vegetables, including kale, collard greens, cabbage, brussels sprouts, kohlrabi, and cauliflower.

cryoablation The elimination of a tissue or a group of cells by directed localized freezing.

crypt A deep cavity in the wall of the small or large intestine in which enterocyte stem cell proliferation and initial differentiation occur.

cutaneous Referring to the skin.

cyclin A protein that associates with a cyclin-dependent kinase and serves as a regulatory subunit of this kinase by activating its catalytic activity and directing it to appropriate substrates. *See also* **cyclin-dependent kinase**.

cyclin-dependent kinase Type of serine/threonine kinase deployed by the cell cycle machinery that depends on an associated cyclin protein for proper functioning. *See also* **cyclin**.

cycloheximide Drug that prevents the forward movement of ribosomes down mRNA templates, thereby blocking protein synthesis.

cyclooxygenase An enzyme that converts arachidonic acid to a number of prostaglandins including prostaglandin E_2.

cyclopia Malformation of the head resulting in embryos with only a single, centrally located eye.

-cyte Suffix indicating a type of cell.

cytoarchitecture Physical structure of a cell.

cytochrome P450enzymes A family of enzymes that function to oxidize steroids, fatty acids, and xenobiotics, and thereby aid in the clearance of various compounds.

cytocidal Referring to an effect or influence that causes cell killing. *See also* **cytopathic**, **cytostatic**, **cytotoxic**.

cytogenetics The study of cell or organismic genetics by examining the microscopic appearance of the chromosomes within individual cells.

cytokeratin Forms of the intermediate filament protein keratin that constitute part of the cytoskeleton of an epithelial cell; term used to distinguish it from the keratins that constitute hair, nails, and feathers.

cytokine (1) Secreted protein that operates like growth factors to stimulate or inhibit various cell types, notably those constituting various branches of the hematopoietic and immune systems. (2) Less commonly, secreted proteins that convey signals between cells, including mitogenic growth factors.

cytokine release syndrome Condition representing acute systemic inflammation associated with fever and often the dysfunction of multiple organs throughout the body, which is often life-threatening.

cytokinesis The late step of mitosis involving the separation of the two daughter cell cytoplasms from one another.

cytology (adj., **-logical**) (1) Analysis of subcellular structure under the microscope. (2) The microscopic appearance of a cell.

cytopathic Causing damage or death to a cell. *See also* **cytocidal**, **cytostatic**, **cytotoxic**.

cytoskeleton Network of filamentous proteins in the cell cytoplasm that provides it with structure and rigidity enables it to exhibit motile behavior and is formed from polymerized actin, tubulin, and intermediate filament proteins such as cytokeratins.

cytosol Portion of the cytoplasm that contains soluble material untethered to either cytoskeleton or membranes including those associated with organelles.

cytostasis The halting of cell proliferation. *See also* **cytostatic.**

cytostatic Referring to an influence or a force that inhibits cell proliferation without necessarily having any effect on cell viability. *See also* **cytocidal**, **cytopathic**, **cytotoxic**.

cytotoxic Referring to the ability of an agent to kill cells; such an agent might be, for example, a drug or another type of cell. *See also* **cytocidal**, **cytopathic**, **cytostatic**.

D-loop The loop of ssDNA created in telomeres through invasion of the telomeric dsDNA by the 5′ ssDNA overhang of the G-rich strand; *also termed* **displacement loop**.

de novo (1) Arising or formed anew. (2) Occurring for the first time.

***de novo* methyltransferase** An enzyme that attaches a methyl group to the C of a CpG dinucleotide in the absence of methylation of the complementary CpG.

deacetylase Enzyme that removes acetate groups from substrates, notably those groups that were previously attached by acetyltransferases. *See also* **acetyltransferase**.

deamination Loss or removal of an amine group from a larger molecule such as a DNA base.

death receptor A family of mammalian transmembrane receptors that function at the cell surface to initiate apoptosis through the extrinsic apoptotic program following binding of their cognate ligands. Examples of death receptors are TNFR1, FAS, DR3, DR4, and DR5.

debulk To reduce in overall size with the intent of removing the great majority of a mass such as a solid tumor.

decatenation Untangling and separation of topologically intertwined circular dsDNA molecules from one another, often accomplished by the topoisomerase II enzyme. *See also* **topoisomerase**.

deconvolute Mathematical manipulation that allows the dissection of complex datasets into distinct subsets of data, often yielding an assessment of the contributions of the individual subsets to the initial data set being analyzed.

decoy receptor A nonsignaling protein that binds and sequesters a ligand (e.g., a growth factor), thereby diverting the ligand from binding and activating its functional cognate signaling receptor.

dedifferentiation Reversion of a more differentiated cell to the phenotype of a less differentiated cell, such as its stem cell precursor.

degranulation Discharge of the contents of cytoplasmic granules into the extracellular space in response to a physiological stimulus.

delayed early Referring to genes whose expression depends on prior *de novo* protein synthesis and is induced with some delay following growth factor stimulation of a factor-starved cell. *See also* **immediate early**.

demineralize To dissolve the inorganic apatite (i.e., calcium phosphate) component, notably of bone.

denaturation Process that causes a molecule, such as a macromolecule (DNA, RNA, or protein), to lose its natural three-dimensional structure.

dendritic cell An innate immune cell that phagocytoses fragments of cells or infectious agents and then proceeds within lymphoid tissues to present oligopeptides derived from these phagocytosed particles to several types of T cells.

dendrogram Diagram in which closely related entities, such as genes, cells, or organisms, are placed close to one another on the branches of a multibranched tree on which the lengths of branches and the number of branch points provide an indication of the degree of relatedness. *See also* **hierarchical clustering**.

density inhibition *See* **contact inhibition**.

denuding Removal or stripping away of a tissue or population of cells, such as those forming an epithelium.

dependency Property of a tumor or tumor cell that reflects its continued dependence on an alteration acquired during the course of its formation and, in turn, renders it vulnerable to a specific type of therapeutic intervention.

dependency map The product of an effort to systematically catalog the effects of chemical and genetic perturbations on a large set of human cancer cell lines. The chemical perturbations derive from measurements of large collections of low–molecular-weight drug molecules, whereas the genetic perturbations derive from CRISPR/Cas9-mediated systematic inactivation of a large collection of genes in the human genome.

depurination Breakage of the glycosidic bond that links purine bases to the deoxyribose or ribose of DNA or RNA, respectively.

depyrimidination Breakage of the glycosidic bond that links pyrimidine bases to the deoxyribose or ribose of DNA or RNA, respectively.

derivitization The alteration via synthetic organic chemistry of the molecular structure of an existing drug molecule, usually through the covalent linkage of side groups, and undertaken with the intention of improving its pharmacological properties.

dermis (adj., **dermal**) Thick layer of stromal cells, largely fibroblasts, found beneath the epidermal keratinocyte layer of the skin.

desmoplastic Referring to a hard extracellular matrix that is rich in collagen and myofibroblasts.

detoxify To render a previously toxic substance harmless.

development The processes of growth, differentiation, and morphogenesis that enable a zygote to develop into a fully formed embryo and thereafter a newborn.

diagnostic bias Tendency of an observation or conclusion to be influenced by the specific properties or applications of a diagnostic technique rather than to accurately reflect an intrinsic property of the entity (such as a disease) under examination.

diapedesis Complex sequence of steps enabling leukocytes to extravasate rapidly from the lumen of a blood vessel through the vessel wall into the underlying tissue parenchyma.

dicentric Referring to a chromosome or chromatid that bears two distinct centromeres.

differentiation Process whereby a cell acquires a specialized phenotype, such as a phenotype characteristic of cells in a particular tissue.

differentiation antigen Protein or other product that is expressed only in a specific stage of differentiation of a normal tissue and that, for various reasons, may not induce immune tolerance.

dimer Molecular complex composed of two subunits.

dioxygenase An oxygenase that catalyzes the introduction of both atoms of molecular oxygen into the substrate being oxidized.

diploid Describing a genome in which all chromosomes are present in pairs, one of each pair being inherited from a father and the other from a mother, with the exception of the sex chromosomes, which in placental mammals are paired in either the XX or the XY configuration.

dirty drug A drug species that inhibits molecules within a cell in addition to its intended major target.

discoldin domain receptor A cell surface tyrosine kinase receptor that recognizes and binds extracellular collagen as its activating cognate ligand.

disease-free survival Time period elapsed following initiation of treatment during which there are no apparent symptoms of the disease under treatment. *See also* **overall survival** and **progression-free survival**.

displacement loop *See* **D-loop**.

disseminated Spread or seeded, often widely throughout the body.

DNA chip An array of thousands of sequence-specific DNA segments, constituting a DNA microarray, that is mounted on a solid support, such as a microscope slide. *See also* **microarray**.

dominance *See* **dominant**.

dominant (1) Referring to one of several alternative traits (phenotypes) that can be specified by a genetic locus; when the locus is heterozygous and carries information specifying two distinct traits, the dominant trait will be the one actually exhibited. (2) Describing an allele of a gene that determines phenotype in spite of the concomitant presence of a second allele, considered to be recessive, that specifies a different, alternative phenotype. *See also* **recessive**.

dominant-interfering *See* **dominant-negative**.

dominant-negative Referring to a mutant allele of a gene that, when co-expressed with the wild-type allele of the gene, is able to interfere with the functioning of the latter. *Also termed* **dominant-interfering**.

dorsal (1) Term for the surface of a cell that is exposed upward away from the underlying physical substrate to which the cell is attached, e.g., the bottom surface of a Petri dish. (2) Anatomical term referring to the back side of an organism such as a mammal. *See also* **ventral**.

dose escalation The practice of progressively increasing the dosage of a drug in an investigatory clinical trial in order to determine efficacy of the drug under study at various applied doses and, at the same time, revealing the toxicity of such doses in order define the maximum tolerated dose. *See also* **maximum tolerated dose.**

dose-limiting toxicity Side effect toxicity that dictates the highest dosage of a drug that can be applied without creating unacceptable levels of such toxicity in a patient. *See also* **maximum tolerated dose**.

double-minute A chromosomal segment that becomes separated from the chromosome in which it normally resides and is able to perpetuate itself as an extrachromosomal particle unlinked to a centromere, so termed because it is visualized at metaphase as small spots that are doubled like the chromatids prior to anaphase.

draining lymph node A lymph node that receives cells and debris via a lymph duct that drains lymphatic fluid from a specific tissue or sector of a tissue.

driver gene A gene that is affected by driver mutations and is identified because the mutations affecting this gene occur more frequently in tumors than would be expected by random chance; driver genes are mutated on a recurring basis in the genomes of multiple, independently arising tumors, ostensibly because these mutations confer advantageous cell phenotypes. *See* **driver mutation**.

driver mutation Mutation creating an allele of a gene that is advantageous for the cell that sustains it and results in clonal expansion of the progeny bearing mutant alleles of this gene. *See also* **driver gene**, **passenger gene**.

drug holiday Defined period when drug treatment is halted.

druggable Referring to a molecular species, such as a protein, that has the structural and functional properties suggesting that low–molecular-weight therapeutic drug compounds can be developed that specifically interact with and perturb its functioning; the structural properties include, most prominently, a drug-binding pocket that should permit high-affinity, multivalent associations between a drug molecule and the targeted protein.

dual-address Referring to signaling that involves the translocation of a protein from one intracellular site to another, e.g., from the cytoplasm to the nucleus.

duodenum (adj., **duodenal**) The section of the small intestine beginning immediately after the stomach and extending as far as the jejunum.

dysbiosis Referring to a shift in the representation of microbial species forming a microbiome away from its natural or optimal configuration.

dyskeratosis congenita An inherited syndrome involving compromise of multiple organs caused by a congenital inability to maintain telomeres in multiple cell types; the disease is often manifest in bone marrow failure and elevated risk of developing certain types of cancer.

dyskerin Protein that is a component of the shelterin complex whose absence causes, among other defects, a loss of proper telomere maintenance and the syndrome of dyskeratosis congenita. *See* **dyskeratosis congenita, shelterin**.

dysplasia (adj., **-plastic**) A premalignant tissue composed of abnormally appearing cells forming a tissue architecture that deviates from normal.

ectoderm Outermost layer of cells in an early chordate embryo that gives rise to the skin and nervous system.

ectodomain Portion of a cell surface protein that protrudes from the plasma membrane into the extracellular space.

ectopic (1) Referring to the expression of a gene or protein in a location or physiological situation where it normally would not be expressed. (2) Referring to the presence of cells or tissues in an anatomical site where they would not naturally be found in the body. *See also* **orthotopic**.

effector An agent (such as a protein) that carries out the actual work of a biological process rather than simply regulating it.

effector function The functions of an immune cell that enable it to interact with various antigen-displaying entities in the body and, in response, execute a specific physiological operation.

effector loop Region of a Ras protein that participates in direct physical interaction with one of its effector proteins; such interaction usually leads to the physical relocalization and/or functional activation of an effector protein.

effector T cells Referring to a group of relatively short-lived T cells types that actively respond to physiological stimuli by executing one or another immunological function; these include CD4+, CD8+, and T_{reg} cells.

efferent Referring to outgoing signals. *See also* **afferent**.

efficacy Measure of the ability of a therapeutic agent to elicit a desired clinical response.

electrophilic Referring to a molecule that seeks out and reacts with electron-rich substrates or molecular partners.

electrophoresis Procedure used to resolve molecules of differing masses, usually macromolecules, by placing them in an electric field that causes them to migrate at different rates through a matrix, such as an agarose or acrylamide gel; larger molecules are retarded by the pores of the gel, while smaller molecules migrate rapidly through the gel.

electroporation Procedure used to introduce various types of molecules into cells via the application of an electrical pulse that briefly opens pores in the plasma membranes of cells.

embolization Process of forming an embolus. *See* **embolus**.

embolus (pl., **emboli**) A blood clot or other solid body, such as a clump of cells, that can travel from one site in the body via the circulation to a second site in which it may become lodged within a blood vessel. *See also* **microembolus**.

embryonic stem cell A cell that derives from the inner cell mass of an early embryo and exhibits pluripotent powers, being able to spawn derivatives that can differentiate into all the cell types of an embryo except the placenta. *See also* **pluripotent**.

emergent Arising out of.

-emia Suffix denoting an excess of a substance or a cell type in the blood.

encapsidation Process of packaging a viral genome in a capsid.

end-replication problem Inability of the main DNA replication machinery to completely copy the end of one of two DNA strands being replicated, specifically the strand bearing a 3’ nucleotide at its end.

endocrine (1) Referring to a gland that secretes substances into the general circulation and thus to the rest of the body. (2) Referring to the signaling path of a hormone or factor that is made by cells in a tissue, passes through the circulation, and affects the behavior of cells in another tissue at a distant anatomical site. *Compare* **autocrine**, **exocrine, intracrine**, **juxtacrine**, **paracrine**.

endocytosis Uptake by a cell of extracellular material together with associated extracellular fluid that is achieved through the invagination of a patch of plasma membrane, thereby yielding membrane-bound vesicles termed endosomes within the cytoplasm. Pinocytosis and phagocytosis are forms of endocytosis. *See also* **exocytosis**, **endosome**, **phagocytosis**, **pinocytosis**.

endoderm Innermost layer of cells in an early embryo, which in chordates serves as precursor of the gastrointestinal tract and associated tissues, including the lungs, liver, and pancreas.

endogamy The practice of marrying within one’s own ethnic group, tribe, or clan.

endogenous Originating from within a cell, tissue, or organism.

endogenous provirus The provirus of a retrovirus that is integrated into the germ line DNA of an organism, thereby assuming a configuration much like all cellular genes in the organism’s genome.

endogenous retroviral genome *See* **endogenous provirus**.

endometrium Epithelial lining of the uterus.

endonuclease An enzyme that cleaves a single- or double-strand nucleic acid at an internal site rather than degrading it from an end. *See also* **exonuclease**.

endoplasmic reticulum Elaborate network of membranous structures in the cytoplasm in which glycoproteins are assembled by specific proteolytic cleavage and covalent attachment of carbohydrate side chains prior to being transported via membranous vesicles to the cell surface.

endoreduplication Process whereby a genome or chromosomal segment is replicated without subsequent segregation of the replicated copies during mitosis.

endosome Membranous vesicle lying beneath the plasma membrane that is formed after a patch of the plasma membrane invaginates into the cytoplasm via the process of endocytosis and pinches off from the plasma membrane into the cytoplasm, carrying with it extracellular fluid and associated molecules. *See also* **endocytosis.**

endothelial cells (1) Mesenchymal cells that form the walls of capillaries or lymph ducts by assuming shapes that allow the assembly of tubelike structures. (2) Mesenchymal cells lining the luminal walls of larger blood vessels or lymph ducts.

enhancer A relatively short sequence of nucleotides near or within a gene to which a transcription factor may bind in a sequence-specific manner and in turn influence the transcription of this gene. *See also* **super-enhancer, transcription factor**.

enterocyte Epithelial cell lining the luminal wall of the gastrointestinal tract or associated structures such as villi.

eosinophil, eosinophile A motile phagocytic granulocyte that can migrate from blood into tissue spaces, displays cell surface IgE receptors, and plays a role, among other functions, in eliminating parasitic and bacterial infectious organisms.

ependymoma A tumor deriving from glial cells and resembling the ependymal cells lining the ventricles of the brain.

epiblast Outer layer of primitive mammalian embryo that gives rise to the three major cell lineages following gastrulation.

epidermis (adj., **-dermal**) The epithelial layer of the skin, composed largely of keratinocytes at various stages of differentiation.

epigenetic (1) Referring to a process that affects phenotype without the involvement of heritable changes in the nucleotide sequence of the genome. (2) Referring to a mechanism enabling the transmission of a heritable trait from a cell or organism to its progeny that does not depend directly on changes of specific nucleotide sequences in its genome. (3) Referring to a mechanism that creates a cell-heritable trait, as in (2), and maintains expression of this trait in the absence of ongoing exposure to the stimulus that initially induced the expression of this trait. *See also* **epigenetics**, **genetic**.

epigenetics (1) The study of cell-heritable changes in gene expression that are not attributable to alteration in the primary DNA sequence. (2) More broadly, the study of changes in phenotype that reflect nongenetic alterations in the cell or organism; *also termed* **epigenomics**. (3) The study of the covalent modifications of histones forming the chromatin and resulting changes in transcriptional regulation.

epigenome The entire ensemble of modifications of a genome that do not affect its nucleotide sequences, such as methylation of CpG dinucleotides in the DNA and modifications of chromatin-associated proteins, notably histones. The epigenome is presumed to dictate the transcriptome of a cell, that is, the pattern of expression of a cell's repertoire of genes. *See also* **transcriptome**.

episome (adj., **episomal**) A genetic element, implicitly formed of dsDNA, that exists in a cell, often over multiple cell generations, but is not physically linked via covalent bonds to the cell's chromosomal DNA.

epistasis (adj., **epistatic**) The masking of the phenotypic effect of the allele(s) of one gene by the allele(s) associated with another gene.

epithelial–mesenchymal transition Cell-biological program enabling acquisition by epithelial cells of some of the phenotypes of mesenchymal cells such as fibroblasts. *Compare* **mesenchymal–epithelial transition**.

epithelium (pl., **epithelia**) A layer of cells that forms the lining of a cavity or duct and the specialized epithelium that forms the skin.

epitope (1) A specific chemical structure—often a short oligopeptide segment of a larger protein antigen—that is recognized and bound by an antibody molecule or other antigen-specific immune molecules. (2) Less commonly, the portion of a molecule that stimulates a specific immune response.

ER stress Physiological stress in the lumen of the endoplasmic reticulum often triggered by misfolded or unfolded protein domains. *See also* **unfolded protein response**.

eraser Enzyme that removes specific covalent modifications from histones within nucleosomes, thereby influencing processes such as transcription, DNA repair, further histone modifications, or DNA methylation. *See also* **writer**, **reader**.

erythroblastosis Malignancy of the precursors of red blood cells, usually referring to a condition of birds.

erythrocyte Red blood cell.

erythroleukemia A leukemia of the nonpigmented precursors of red blood cells.

erythropoiesis Process by which red blood cells are formed.

erythropoietin Growth factor that stimulates the production of red blood cells, often in response to inadequate oxygen transport by the blood.

essential genes The collection of genes that is required for normal organismic development and viability or for normal cellular viability or behavior. *See also* **essentialome**.

essentialome The collection of genes present in the genome of a cell or organism that is critical to its viability. *See also* **essential genes**.

estradiol 17b-Estradiol, *commonly called* **estrogen**. *See also* **estrogen**.

estrogen Steroid hormone that controls development of a variety of tissues including those involved in female development and reproductive function. *See also* **estradiol**.

etiology (adj., **-ologic**) (1) Mechanism or agent that is responsible for causing a specific pathological state. (2) The study of causative mechanisms of pathology.

euchromatin Chromatin that contains transcriptionally active genes and is therefore relatively expanded (rather than being condensed) and stains lightly. *See also* **heterochromatin**.

eukaryotic Referring to the large, complex, nucleated cells of metazoa, metaphyta, and many protozoa. *See also* **prokaryotic.**

euploid (1) Referring to a collection of chromosomes that corresponds precisely in number and structure to the array present in normal, wild-type cells. (2) Describing a karyotype having such a complement of chromosomes. *See also* **karyotype.**

event-free survival Period after initial treatment during which no additional clinical indications or episodes of disease are registered.

ex vivo Occurring outside of a living body or organism. *Compare in vitro, in vivo*.

executioner caspases A family of proteases (including caspases 3, 6, and 7) that become activated by initiator caspases through proteolytic cleavage and

subsequently cleave a number of cellular target proteins, leading to cell death. *See also* **caspase**.

exhaustion (adj. **exhausted**) Physiological state of a T cell that has lost many of its normally exercised effector functions; provoking signals include chronic antigen stimulation and prolonged contact with antigen-presenting cells. Less commonly, NK cell exhaustion and macrophage exhaustion.

exocrine Referring to a gland that secretes fluids via a duct, often into the gastrointestinal tract or to the surface of the skin, rather than into the bloodstream. *Compare* **autocrine**, **endocrine**, **intracrine**, **juxtacrine**, **paracrine**.

exocyclic Referring to a chemical group that protrudes from the ring moiety of a molecule such as a DNA base.

exocyst Multi-subunit cytoplasmic protein complex that enables the tethering to the inner surface of the plasma membrane of vesicles destined for exocytosis, thereby regulating the cell surface display and secretion of a broad range of signaling molecules. *See* **exocytosis**.

exocytosis (1) Process by which cells secrete soluble products by storing them in the lumina of cytoplasmic exocytic vesicles that are caused to fuse with the plasma membrane, allowing the products carried within these vesicles to be released into the extracellular space. (2) Process by which cells achieve the display of proteins on the cell surface by embedding them in the membranes of exocytic vesicles prior to fusion of the latter with the plasma membrane. *Compare* **endocytosis**. *See also* **exocyst**.

exogenous Originating from outside a cell, tissue, or organism.

exome The collection of all exon segments present in a cellular transcriptome. *See also* **exon**, **transcriptome**.

exon Portion of a primary RNA transcript that is retained in the RNA product of splicing. *See also* **intron**.

exonuclease An enzyme that degrades a polynucleotide, often by proceeding processively (nucleotide-by-nucleotide) from one end or the other. *See also* **endonuclease**.

exosomes Small (30- to 100-nm) membrane vesicles that are released by many cell types into the extracellular space, following which they may adsorb to and fuse with other cells, thereby conveying molecular cargo into the latter.

experimental metastasis Procedure for introducing cancer cells into the circulation via injection into the tail vein of a mouse; this procedure largely yields cancer cells trapped in the microvessels of the lungs.

expression (1) Transcription of an active gene or synthesis of a protein from its encoded mRNA. (2) Forced release of interstitial fluid from a tissue caused by contraction of cells and/or extracellular matrix in that tissue. *See also* **repression**.

expression array A collection of probes that enables the concomitant measurement of the expression levels of a large group of genes, often encompassing more than 10,000 genes, that are transcribed in a cell type or tissue.

expression program The coordinated expression of a series of genes.

expression signature A constellation of up-regulated and down-regulated genes that can be correlated with a defined biological phenotype.

expressivity The quantitative extent to which a measurable or observable phenotype is expressed by an individual or cell carrying a specific allele or gene. *See also* **penetrance**.

external beam therapy Form of radiotherapy, in which the radiation source is usually a linear accelerator used as the source of radiation that is usually directed in a highly focused fashion to a region of tissue that is being treated.

extracellular matrix Meshwork of secreted proteins, largely glycoproteins and proteoglycans, that surrounds most cells within tissues and creates a structural scaffold in the intercellular space.

extravasation Process of leaving a blood or lymphatic vessel and invading the parenchyma of the adjacent tissue. *See also* **intravasation**.

F-actin The polymerized form of actin that forms filament. *See also* **actin**.

facultative heterochromatin Referring to chromatin that can switch from a heterochromatic to a euchromatic state in response to physiologic or developmental signals. *See also* **constitutive heterochromatin**, **euchromatin**.

familial Referring to an organismic trait or a syndrome that is heritable and therefore found in clusters in certain families.

familial adenomatous polyposis An inborn condition resulting in the formation of many hundreds of colorectal polyps, some of which are poised to progress to frank colorectal carcinomas. *See also* **hereditary non-polyposis colorectal cancer**.

Fc receptor A cell surface protein displayed by immunocytes, such as NK cells, dendritic cells and macrophages, that recognizes and binds the constant regions of antibody molecules, notably IgG molecules, the latter being bound via their variable regions to antigens on the surfaces of potential target cells such as microbes or cancer cells; such binding enables killing of the antibody-bound cells by the NK cells or macrophages.

Fc region Domain of an antibody molecule, notably that of IgG molecules, that is formed by the H-chain constant region and is recognized, when bound to a cell surface, by Fc receptors. *See also* **Fc receptor**.

feeder layer A population of cells, usually grown as a monolayer, that continuously secretes factors that benefit the growth and survival of a second cell population that is propagated above this monolayer.

feedback A regulatory interaction in which the stimulation of one component of a regulatory circuit enables this component to either stimulate or shut down further signaling by the source of the initial stimulation. *See also* **positive feedback, negative feedback, feedforward**.

feedforward Alternative term for **positive feedback**.

fenestration An opening in a surface, such as one found in the wall of a blood vessel.

ferroptosis A form of programmed cell death that depends on iron and the formation of lipid peroxides and is distinct from other forms of cell death such as apoptosis. *See also* **apoptosis, necroptosis, pyroptosis**.

fibrin Protein that is formed by the cleavage of plasma fibrinogen and assembles to form the fibers binding the platelets together in clots.

fibrinogen *See* **fibrin**.

fibrinolysis Dissolution of fibrin bundles achieved by certain proteases.

fibroblast Mesenchymal cell type that is common in connective tissues and in the stromal compartment of epithelial tissues and is characterized by its secretion of collagen.

fibrocyte A relatively undifferentiated circulating cell derived from monocytes in the bone marrow that expresses collagen, adheres tightly to substrates when cultured *in vitro*, exhibits certain features usually associated with macrophages, and serves as the precursor of fibroblasts and/or myofibroblasts in tissues to which it has been recruited.

fibroma A benign tumor of mesenchymal tissue containing fibroblast-like cells.

fibrosis Development within a tissue, often following chronic inflammation, of dense fibrous stroma that replaces normally present epithelium, resulting in loss of function of that tissue.

field cancerization Phenomenon in which an outwardly normal region of an organ or tissue produces multiple, ostensibly independently arising premalignant growths or frank neoplasms that actually share a common clonal origin and share a common set of abnormalities, including somatic mutations. Field cancerization is presumed to reflect the proliferative and survival advantage of somatic mutations (or heritable changes in the epigenome) that are not manifested in the outward behavior of the affected cells, but were already widely dispersed in this region prior to the appearance of these clearly preneoplastic or frankly neoplastic outgrowths. *See also* **clonal hematopoiesis**.

filopodium Filamentous, spikelike protrusion from the surface of a cell, usually extending from the leading edge of a lamellipodium, that may be used by the cell to explore territory that lies ahead in its path and to forge focal adhesions with the extracellular matrix lying in this path. *See also* **lamellipodium**.

filtrate Liquid that has passed through a filter.

first-degree relative A parent, sibling, or offspring of an individual (all of whom share 50% of their genome with the individual).

first-line therapy The mode of therapy that is initially employed to treat a patient, usually because it is considered most likely to elicit a desired clinical response; failure of this initial therapy often leads to the use of second-line treatments. *See also* **second-line therapy**.

fitness (1) Term to reflect the likelihood that, during the course of evolution, an organism will leave more descendants within a species as a consequence of its increased adaptation to the environment in which it exists or elevated ability to compete successfully with other similar individual organisms within the species. (2) Similar dynamics applying to the ability of an individual cancer cell or group of cancer cells to outcompete other such cells within a tumor.

fixed To become stably established, such as established within the genome of a cell or species.

floxed Referring to a gene or genetic segment that is flanked on both sides by LoxP sites. *See* **loxP**.

fluorescence *in situ***hybridization** Procedure in which a sequence-specific DNA probe linked to a fluorescent chromophore is annealed to the DNA or RNA of cells that have been immobilized on a microscope slide, revealing via resulting fluorescing spots the presence and often the number of copies of homologous DNA/RNA sequences carried by such cells that have annealed to the DNA probe.

fluorophore A molecule that fluoresces in response to exposure to light of a certain wavelength.

focal Referring to a change that affects only a small region or area, such as a relatively short segment of a chromosome.

focal adhesion A multiprotein complex containing many dozens of protein species that is assembled after a cell surface integrin binds macromolecular components of the extracellular matrix (ECM); focal adhesions mediate physical anchoring of a cell to the adjacent ECM, as well as transmitting information about this anchoring to the cell interior.

focus (pl., **foci**) A cluster of transformed cells growing amid a surrounding monolayer of normal untransformed cells in culture. Individual foci are usually composed of the lineal/clonal descendants of a founding cell that was transformed by one or another transforming agent.

founder effect Phenomenon in which multiple individuals within a species, often not known to share any genealogical relationship with one another, are found to carry a common germ-line allele that testifies to their actual descent from a common ancestor that bore the allele.

fragile site A site along a chromosome that is intrinsically unstable and thus especially susceptible to breakage, the existence of which is often revealed when DNA replication forks proceeding through the site are stalled.

frameshift A mutation that disrupts the reading frame of the coding sequence of a gene, doing so by adding or subtracting nucleotides that are

not multiples of 3. *See also* **reading frame**.

Frizzled Referring to a class of 7-membrane-spanning cell-surface proteins that function as receptors for Wnt ligands.

frontline therapy *See* **first-line therapy**.

functional genomics (1) Technology in which cell phenotypes are gauged by measuring the expression level of multiple genes, usually numbering in the thousands, in the cells. (2) Such analysis performed comparatively by examining various cell types or tissues that exist in different physiologic, pathological, or developmental conditions. (3) Study of how specific transcriptional programs contribute to the expression of specific functions or phenotypes.

fusogenic Capable of causing the fusion of membranes, such as the plasma membranes of two closely apposed cells.

G-protein A signaling protein that actively emits signals when it has bound GTP and shuts itself off by hydrolyzing the GTP, yielding bound GDP and transition of the protein to its inactive, non-signaling state. *See also* **guanine nucleotide exchange factor**.

gain-of-function Referring to a mutation that imparts novel activity to a gene and encoded protein. *See also* **loss-of-function**.

gametogenesis Processes that yield gametes, i.e., sperm or eggs.

ganglion (pl., **ganglia**) Cluster of neuron cell bodies formed in various parts of the peripheral nervous system and, to a smaller extent, in the central nervous system.

gasdermin A membrane pore-forming protein that is activated as part of the pyroptosis program. *See also* **pyroptosis**.

gastric Referring to the stomach.

gastrulation An early stage of embryogenesis in which cells of the outer ectodermal layer invaginate into the interior of the embryo, where they

serve subsequently as precursors of the endodermal and mesodermal cell layers.

gatekeeper (1) An oligopeptide domain that controls access by small molecules to the catalytic cleft of an enzyme such as a kinase. (2) A gene that operates to regulate cell proliferation or to regulate cell number by controlling cell differentiation or cell death. Loss of a gatekeeper gene removes an impediment to cell proliferation and thus to the appearance of populations of neoplastic cells. *Compare* **caretaker**, **tumor suppressor gene**.

gatekeeper mutation A mutation that restricts the accessibility of the ATP-binding pocket in the catalytic cleft of a protein kinase and thereby reduces the efficacy of a kinase-inhibiting drug designed to be bound in that cleft.

gene amplification *See* **amplification**.

gene conversion Process whereby the genetic information on one chromosome is transferred to the homologous chromosome without genetic recombination or crossing over occurring between the two chromosomes.

gene family Group of genes all of which are descended evolutionarily from a common ancestral gene. The members of a gene family generally encode distinct, structurally related proteins.

gene pool Collection of genes and associated alleles that are carried by the members of a species or by a group of individual organisms.

gene set enrichment analysis A computational algorithm designed to determine whether a set of genes is associated with a specific biological function or phenotype.

gene therapy Therapeutic strategy that involves the introduction of a cloned gene into cells of a diseased tissue, undertaken with the anticipation that the introduced gene will reverse a disease condition.

general transcription factor A protein that associates with sequence-specific transcription factors throughout the genome to enable transcription

to occur; general transcription factors usually do not possess sequence-specific DNA-binding domains and are presumed to be responsible for regulating the expression of large numbers of genes, possibly in certain cases all of the actively transcribed genes in a cell. *See also* **transcription factor**.

genetic (1) Involving the action of genes and the information that they carry. (2) Depending directly on the DNA and the nucleotide sequences that it contains. *See also* **epigenetic**.

genetic background The entire array of alleles carried in a cell or organismic genome with the exception of a gene or a small number of genes that are the subject of study.

genetic polymorphism A genetic element that is present in the gene pool of a species in multiple variant forms. Polymorphisms are often implied to have small or no effects on phenotype or evolutionary fitness. *See also* **polymorphism**.

genomic clone The product of a procedure involving recombinant DNA techniques that produces many copies of a specific segment of an organism's genome (e.g., its chromosomal DNA) through experimental isolation and amplification.

genotoxic Referring to an agent or mechanism that is capable of damaging a genome, i.e., is mutagenic.

genotype Genetic constitution of a cell or an organism.

germ cell An egg (ovum) or sperm (spermatocyte) or its immediate precursor within the ovary or testis, respectively.

germ line (1) The collection of genes that is transmitted from one organismic generation to the next. (2) The cells within a multicellular organism that are responsible for carrying and transmitting genes from one organismic generation to its offspring.

germ-line chimera An organism in which the germ cells derive from more than one genetic background.

germinal center Site in spleen or lymph node in which B cells differentiate, assemble, and diversify their antibody genes, and proliferate.

Giemsa A blue stain that is specific for DNA, binding preferentially to segments that are high in adenine and thymine.

glioblastoma A malignant high-grade glioma that often originates from a low-grade astrocytoma. *Also termed* glioblastoma multiforme. *See also* **glioma**.

glioma A group of central nervous system tumors that arise from glial cells and include ependymomas, astrocytomas, and oligodendrogliomas. *See also* **glioblastoma**.

global genomic repair Form of nucleotide excision repair that operates on all parts of the genome.

glutathione-*S*-transferase A family of enzymes that catalyze the conjugation of the reduced form of glutathione (GSH) to xenobiotic compounds for the purpose of detoxification.

glycolysis The series of enzymatic reactions in the cell cytoplasm that leads to the progressive degradation of a glucose molecule into three- and two-carbon fragments with the generation of ATP and NADH; glycolysis can proceed in the absence of available oxygen.

glycoprotein A protein that has been modified post-translationally through the covalent linkage of polysaccharide trees to the amino-acid side chains of the protein, usually those of asparagine, arginine, or serine. *See also* **glycosylation**.

glycosaminoglycan A charged polysaccharide of the extracellular matrix, such as chondroitin sulfate, hyaluronic acid, or heparin, that is attached covalently to a protein core and is composed of repeating monosaccharides, some of which are amino sugars. *See also* **proteoglycan**.

glycosylase An enzyme that cleaves a glycosidic bond, such as that linking a purine or pyrimidine base to a ribose or deoxyribose sugar.

glycosylation Covalent attachment of a carbohydrate side chain, usually a covalently linked branched network of monosaccharides, to a second molecule, e.g., to the side chain of an asparagine residue of a protein; such attachment occurs in concert with or following initial synthesis of the polypeptide backbone of a protein.

grade Degree or extent to which a tumor has advanced toward a highly aggressive state, as assessed by a pathologist usually on the basis of its histopathological appearance; high-grade tumors are more progressed and generally carry worse prognoses.

graft-versus-host disease A condition, often life-threatening, in which cells of an allogeneic bone marrow graft generate significant immune-mediated destruction of various normal tissues throughout the body of the graft recipient.

graft-versus-tumor An immunological process in which engrafted allogeneic bone marrow cells attack neoplastic cells in the graft recipient, usually the cellular constituents of hematopoietic malignancies; such attack may augment other anti-tumor therapies being applied to the graft recipient and may occur with acceptably low levels of graft-versus-host disease. *See also* **graft-versus-host disease**.

granulocyte Leukocyte that contains cytoplasmic granules, such as a basophil, an eosinophil, or a neutrophil.

granzyme Serine protease that is introduced by cytotoxic lymphocytes and natural killer cells into the cytoplasm of their cellular targets, where it triggers apoptosis by cleaving various cellular proteins, among them caspases.

gray (Gy) Unit of radiation exposure equal to the absorption of 1 joule of energy per kilogram of exposed tissue.

growth (1) Process involving accumulation of cellular constituents and associated increases in cell size such as cell volume. (2) Commonly but inappropriately used term for cell proliferation. *Compare with* **proliferation**.

growth arrest Halting of the progression of a cell through its growth-and-division cycle. *See also* **cytostatic**.

growth factor Secreted protein that is able to stimulate the growth and/or proliferation of a cell by binding to a specific cell-surface receptor displayed by that cell.

GTPase Enzymatic activity that hydrolyzes GTP to GDP.

GTPase-activating protein A protein that interacts with a G-protein and induces the latter to activate its intrinsic GTPase, thereby causing it to hydrolyze its bound GTP and enter into its GDP-bound state. *See also* **G-protein**, **guanine nucleotide exchange factor**.

guanine nucleotide exchange factor Protein that interacts with a G-protein, inducing the latter to release whatever guanine nucleotide it is binding, thereby creating space for another to be bound. Since GTP is present in the cytosol in great molar excess over GDP, this induced change usually results in the replacement of a GDP with a GTP and the associated functional activation of the G protein. *See also* **G-protein**, **GTPase-activating protein**.

hairpin Configuration of a single-stranded RNA or DNA molecule that is able to generate a double-stranded domain through the complementarity of two regions of such a molecule, in effect allowing the two regions to anneal with one another.

half-life (1) Time during which half of a population of metabolically unstable molecules decays or is eliminated or the time required for half of a physiological signal to decrease. (2) Time in which 50% of the atoms of a quantity of a radioactive isotope decay. (3) Time during which half of the entities forming a large population disappear or are removed.

Hallmarks of Cancer A set of cell-biological traits that are shared in common by the neoplastic cells forming a wide range of distinct types of tumors, are required for expression of the neoplastic cell phenotype, and distinguish such cells from the traits of corresponding normal cells.

hamartoma Benign overgrowth of tissue that normally involves mesenchymal cells; for example, gastrointestinal hamartomas are characterized by a benign expansion of stromal cells, often with concomitant hyperplasia of adjacent epithelial cells.

haploid Describing a genome in which all chromosomes are present in a single copy.

haploinsufficiency Genetic condition in which the presence of only a single functional copy of a gene yields a mutant or partially mutant phenotype.

haptotaxis Process in which the direction of migration of a cell is influenced by insoluble molecules in the extracellular space, specifically structural components of the extracellular matrix as well as molecules tethered to this matrix. *Compare* **chemotaxis**.

hard-wired (1) Describing a component of a regulatory circuit that is fixed and not readily changed. (2) Describing a response or behavior that is innate and not readily revised or altered.

hazard ratio The rate at which a given condition or state arises in an experimental population divided by the rate at which this occurs in a matched control population.

head-and-neck cancers A group of carcinomas of the larynx, throat, mouth, nose, and salivary glands.

heat map Graphic representation in the form of a matrix of the results of gene or protein expression analyses, in which a series of gene-specific probes is arrayed in one dimension, a series of biological samples is arrayed in a second dimension, and the intensity of expression is represented by two colors and intermediate shades.

heavy chain Larger of the two polypeptide chains that assemble to form immunoglobulins and related proteins. *Compare* **light chain**.

helicase An enzyme that functions to unwind helices, usually the double helices formed by DNA.

helper T cell A subtype of T cell that is identified by its expression of the CD4 co-receptor and functions to stimulate and amplify the functions of B cells and effector T cells, most importantly the CD8+ cytotoxic T cells.

hemangioblastoma Benign tumor of the precursors of the endothelial cells forming blood vessels within the central nervous system.

hemangioma Benign tumor of endothelial cell origin often seen in infants.

hematogenous Depending upon or facilitated by circulating blood.

hematogenous dissemination Metastatic dissemination occurring via the circulating blood.

hematopoiesis (adj., **-poietic**) Process that results in the formation of all of the cells in the blood, including its red and white cells, the latter including various cells of the immune system.

hemidesmosome A cluster of integrin molecules displayed on the basal surface of epithelial cells and used to anchor these cells to the underlying basement membrane.

hemi-methylated Referring to a DNA molecule in which only one of the two complementary strands of a particular DNA segment is methylated, usually at the deoxycytidine moiety of a CpG dinucleotide sequence.

hemizygosity Presence of only one copy of an autosomal gene per cell.

heparin An extracellular matrix glycosaminoglycan.

hepatectomy Procedure whereby part or all of the liver is surgically excised.

hepatoblast Embryonic liver cell.

hepatocellular carcinoma *See* **hepatoma**.

hepatocyte Epithelial cell type that forms the bulk of the liver and is responsible for virtually all of its metabolic activities.

hepatoma Tumor of the liver; also known as **hepatocellular carcinoma**.

Herceptin Chimeric anti-HER2/Neu monoclonal antibody bearing murine antigen-combining (variable) domains and a largely human constant domain. *Also called* **trastuzumab**.

hereditary non-polyposis colon cancer Inborn condition predisposing to colorectal cancers and distinct from familial adenomatous polyposis, being generally caused by inherited defects in the DNA mismatch repair machinery. *Also termed* **Lynch syndrome**; *See also* **familial adenomatous polyposis**.

heterochromatin Chromatin that contains transcriptionally inactive genes or no genes at all and is condensed and stains darkly. *See also* **euchromatin**.

heterochromatinization The process whereby euchromatin is converted to heterochromatin, notably that occurring during the process of X-chromosome inactivation.

heterocyclic amine Any of various carcinogenic amines formed when creatine or creatinine reacts with free amino acids and sugars in meat cooked at high temperatures.

heterodimer Molecular complex composed of two distinct subunits. *See also* **homodimer**.

heterogenous nuclear RNA (hnRNA) The collection of primary transcripts synthesized by pol II and derived processed intermediates arising from the actively transcribed genes of a cell.

heterokaryon Cell carrying two (or more) genetically distinct nuclei, often arising from the experimental fusion of two cells.

heterotrimer A molecule that is composed of three distinct subunits such as three distinct protein chains.

heterotypic Referring to interactions between two or more distinct cell types. *See also* **homotypic**.

heterozygote Individual cell or organism that carries two distinct alleles of a gene of interest. *See also* **heterozygous**.

heterozygous Referring to the configuration of a genetic locus in which the two copies of the associated gene carry different versions (alleles) of the gene that represents this locus. *See also* **homozygous**.

hierarchical clustering Statistical method used to place more similar samples closer together on a tree (*also called* dendrogram) than less similar samples, which are placed on more distant branches of the tree. *See also* **dendrogram**.

high-grade Referring to a tumor that has progressed through many steps of multi-step tumorigenesis and become highly malignant. *Compare with* **low-grade**.

high-throughput screening Technology involving robotic screening of large collections of pharmacological compounds to identify individual compounds that exhibit properties of a sought-after agent, such as potent inhibition of an enzyme.

histo- Prefix referring to tissue.

histochemistry Use of specific chemicals and chemical procedures to specifically react with and stain subcellular and cellular structures as well as tissues to reveal, when examined under the microscope, the presence of specific types of biological molecules present in these entities.

histocompatible Ability of tissues or cells to be tolerated by the immune system of the host organism into which they are engrafted. *See also* **histoincompatible**.

histocompatibility antigen Cell surface protein that determines whether or not an engrafted cell or tissue will be tolerated by the immune system of a host organism. *See also* **major histocompatibility antigen**.

histoincompatible Failure of tissues or cells to be tolerated by the immune system of the host organism into which they have been engrafted. *See also* **histocompatible**.

histology Study of tissue structure at the microscopic level. *See also* **histopathology**.

histomorphology The shapes and forms of cells and assemblies of cells within a tissue as revealed by microscopic examination of sections of that tissue.

histopathology Study of tissue structure at the microscopic level, often with reference to abnormal tissue. *See also* **pathology**.

Holliday junction Junction formed between four DNA double helices that can serve as an intermediate in certain forms of homologous recombination.

holoenzyme A multi-subunit complex containing an enzyme and associated protein subunits that collaborate to mediate and regulate enzymatic activity.

homeostasis (adj. **homeostatic**) The product of physiological control mechanisms that operate to maintain an optimal, often unchanging level of a certain signaling process, metabolic product, physiological function, or cell type.

homodimer Molecular complex composed of two identical subunits. *See also* **heterodimer**.

homogeneously staining region A region of a chromosome consisting of amplified copies of a chromosomal segment that have become fused end to

end; because each copy contains a characteristic sequence of DNA, the region as a whole appears homogenous following staining.

homolog (*also* **homologue**) A gene that is related to another because of evolutionary descent from a common ancestral gene. *See also* **ortholog, paralog**.

homologous (1) Referring to the relationship between a pair of chromosomes that carry the same set of genes within a diploid cell or organism. (2) Referring to genes or characteristics that are similar in related organisms because of shared descent from a common precursor. (3) Referring to two nucleic acids having similar or closely related nucleotide sequences. *See also* **analogous**.

homology-directed repair Form of DNA repair in which the reconstruction of damaged DNA, often involving a double-strand break, is instructed by the corresponding homologous nucleotide sequences present in the paired, intact sister chromatid.

homophilic Describing a molecule that binds preferentially to one or more additional molecules of the same type.

homopolymer A polymer that is assembled from monomers of a single type, such as an oligonucleotide segment formed entirely from one or another of the four possible deoxyribonucleotides.

homotetramer An assembly of four identical subunits, usually referring to proteins.

homotypic (1) Referring to interactions between two cells of the same type; *See also* **heterotypic**. (2) Referring to interactions between two or more molecules of the same type.

homozygous Referring to the configuration of a genetic locus in which the two copies of the associated gene carry identical alleles of the gene. *See also* **heterozygous**.

horizontal transmission Transmission of an agent, such as an infectious agent, throughout a population in ways that do not depend on parent-offspring interactions. *See also* **vertical transmission**.

hormone response element An oligonucleotide sequence in genomic DNA to which hormone-activated nuclear receptors bind.

host (1) The animal or human that bears a tumor as distinguished from the tumor itself. (2) The animal or human into which cells or molecules are introduced, often by experimentation or infection.

housekeeping gene A gene that is used universally in all cells throughout the body independent of their differentiated state and is assumed to be essential for their continuing viability.

humanize To impart human properties to something, e.g., an antibody molecule.

humanized antibody An antibody molecule of a nonhuman species whose constant (C) region and variable (V) region amino acid sequences outside of the antigen-combining site have been replaced by the homologous sequences of human origin, leaving only the antigen-combining sequences unmodified.

humoral Referring to a soluble substance or a fluid.

humoral immune response The arm of the immune system whose functions are mediated by the antibodies that it produces. *See also* **cellular immune response**.

hyaluronic acid A polymer assembled from disaccharide monomers formed from glucuronic acid plus *N*-acetyl-D-glucosamine.

hybrid (1) An experimentally formed double helix of two complementary nucleic acid strains. (2) A cell arising as a consequence of the experimental fusion of two parental cells that are distinct from one another. (3) An organism that results from the interbreeding of two genetically distinct parents.

hybridization Molecular process involving the annealing of two single-strand nucleic acid molecules to one another that depends on their having mutually complementary sequences and yields a double-stranded helical structure, such as DNA:DNA, DNA:RNA, or RNA:RNA helices.

hybridoma A clonal cell line that derives from the fusion of a plasma cell producing an antibody of interest with a myeloma cell and that is employed for the production of a distinct monoclonal antibody species. *See also* **monoclonal antibody**.

hydrocarbon An organic molecule composed of hydrogen and carbon atoms.

hydrogel A three-dimensional network of highly hydrophilic polymer molecules that can absorb 10- or even 100-fold its mass of water and can serve as an experimental model of natural matrices, such as the extracellular matrix.

hydrolysis Chemical breakdown of a compound through chemical reactions of covalent bonds with water molecules.

hydrophilic Referring to a chemical moiety or environment that prefers direct association with water. *Compare* **hydrophobic**.

hydrophobic Referring to a chemical moiety or environment that avoids direct interaction with water. *Compare* **hydrophilic**.

hypercalcemia Presence of elevated concentrations of calcium ions in the blood.

hypereosinophilic Referring to a syndrome with elevated levels of eosinophils in the circulation. *See* **eosinophil**.

hyperinsulinemia Level of circulating insulin that is higher than would be expected or is physiologically anticipated.

hypermethylation Referring to a state in which the number of CpG sites that are methylated is elevated relative to their number in normal or

reference cells. *Compare* **hypomethylation**.

hyperoxia State of oxygen tension that is elevated above physiological levels.

hyperphosphorylated Referring to the elevated phosphorylation state (e.g., of a protein).

hyperplasia (adj., - **plastic**) (1) Accumulation of excessive numbers of normal-appearing cells within an otherwise normal-appearing tissue. (2) An increase in the size of a tissue or organ, usually due to increased cell number rather than increased size of constituent cells.

hyperthyroidism Condition in which the thyroid gland releases inappropriately high levels of thyroid hormone into the circulation, leading to an elevated metabolic rate and multiple secondary effects on the body.

hypertrophy An increase in the size of a tissue or organ due to increased sizes of component cells rather than increased numbers of cells.

hypomethylation Referring to a state in which the number of CpG sites that are methylated is reduced relative to their state in normal or reference cells. *See* **hypermethylation**.

hypomorphic Referring to an allele that specifies reduced gene function while not eliminating it entirely. *See also* **null allele**.

hypopharyngeal Referring to the region between the pharynx and the entrance to the esophagus.

hypophosphorylated Referring to relatively low level of phosphorylation (of a protein).

hypoxia (adj., **hypoxic**) State of lower-than-normal oxygen tension. *See also* **normoxia**.

idiotype The structure that is created by the amino acid sequences forming the antigen-combining pocket of an antibody molecule; these sequences can

themselves function as antigens that provoke the synthesis of new antibody molecules reactive with the initial antibody molecule.

illegitimate recombination *See* **nonhomologous recombination**.

immediate early genes Referring to the group of genes whose expression is induced within half an hour of growth factor stimulation of previously factor-deprived cells, occurring even when protein synthesis is inhibited. *See also* **delayed early**.

immortal *See* **immortalization**.

immortality Trait of a cell or population of cells that reflects the ability of these cells and their descendants to proliferate indefinitely, usually observed in cell culture.

immortalization Process whereby a cell population normally having limited replicative potential acquires the ability to multiply indefinitely.

immune checkpoint Control mechanism ensuring that immune attacks on cells and tissues are constrained or limited, achieved by modulating downstream signaling responses such as those triggered by receptor–ligand interactions between immunocytes and target cells. *See also* **checkpoint**.

immune tolerance Physiological state that reflects the ability of the immune system to ignore or overlook the body's normal complement of antigens and the cells expressing such antigens.

immunoblot *See* **Western blot**.

immunocompetent Referring to an organism whose immune system is fully functional.

immunocompromised Describing an organism lacking a fully functional immune system. *Also termed* **immunodeficient**.

immunocyte A cell associated with one of the multiple types of cells that form the functional arms of the immune system.

immunodeficient *See* **immunocompromised**.

immunoediting Process in which the selective pressure imposed by immune surveillance and attack eliminates strongly immunogenic tumor cells while permitting the survival and outgrowth of those that are weakly immunogenic.

immunoevasion A biological strategy that enables an abnormal cell or an infectious agent to evade detection and/or elimination by the immune system.

immunofluorescence Use of antibody molecules linked directly or indirectly to fluorescent dyes used in order to stain tissue sections displaying antigens that are specifically recognized by such antibodies.

immunogen (adj., **-genic**) A chemical structure that is capable of provoking some type of immune response, e.g., an antigen that can provoke the synthesis of antibody molecules capable of recognizing and binding it.

immunoglobulin An antibody molecule assembled from two heavy and two light chains.

immunoglobulin superfamily Proteins belonging to a diverse array of cell surface and secreted soluble molecules, including antibody molecules and cell surface B-cell and T-cell receptors. The structural features shared among these proteins indicate that they have evolved from a common precursor and that their respective encoding genes represent paralogs of one another.

immunohistochemistry Procedure in which expression of an antigen is localized in a histological section through the use of an antibody that has been coupled to an enzyme (e.g., horseradish peroxidase) capable of generating a product that is visible in the light microscope.

immunological memory The process by which cells of the adaptive immune system store information of an encounter with an antigen and exploit this stored information to rapidly mount a second immune response

against this antigen long after the initial encounter with the antigen has taken place.

immunophenotyping The process of classifying a cell by determining the spectrum of specific antigens it expresses, usually on its surface.

immunoprecipitation Process of precipitating a molecule or molecular complex using an antibody that specifically recognizes and binds such a molecule or a component of such a molecular complex.

immunoprivileged Referring to sites in the body that are shielded by various mechanisms from routine surveillance conducted by components of the immune system.

immunoproteasome A proteasome that is specialized to generate oligopeptides for eventual presentation by MHC/HLA molecules at the cell surface. *See also* **proteasome**, **constitutive proteasome**.

immunostaining The use of antigen-specific antibodies linked directly or indirectly to fluorophores or dye-activating enzymes to reveal specific cells or subcellular structures present in histological sections.

immunosuppressive Referring to mechanisms and agents that constrain or inhibit the immune response, often involving its adaptive arms

immunosurveillance Process by which the immune system continuously monitors tissues for the presence of aberrant antigens or cells, including cancer cells, and in response, mounts responses to eliminate the antigens or cells expressing such antigens.

immunotoxin Toxin that is targeted to certain tissues or cells because it has been coupled to an antigen-specific antibody, usually a monoclonal antibody.

imprinting Process by which either the paternally or the maternally derived copy of a gene is transcriptionally inactivated during embryogenesis through promoter methylation, ensuring that only a single copy of the gene is expressed in somatic cells.

in situ (1) Occurring in the site of origin. (2) Localized to a specific site. (3) In the case of carcinomas, confined to the epithelial side of the basement membrane.

***in situ* hybridization** Procedure in which a nucleic acid probe is annealed to a nucleic acid (DNA or RNA) while the latter remains localized to its original site within a cell or tissue section; the probe is often linked to a fluorescent dye that can be visualized microscopically or to a radioisotope that can be detected by autoradiography. *See* **autoradiography**.

in utero Occurring in the womb during embryonic or fetal development.

in vitro (1) Referring to biochemical processes, notably reactions, that occur outside of living cells, including in cell lysates or under conditions involving purified reactants. (2) Referring to the propagation of living cells in a vessel (e.g., a Petri dish) rather than in living tissues. *Compare* ***in vivo, ex vivo***.

in vivo (1) Occurring in a living organism. (2) Occurring in a living, intact cell. *Compare in* ***vitro, ex vivo***.

inborn Inherited, congenital.

inbred Referring to a population generated by inbreeding. *See also* **inbreeding**.

inbreeding (1) Breeding of a strain of organisms, such as a strain of mice or rats, with one another in order to achieve genetic identity among all individuals of the strain (with the exception of male/female genetic differences). (2) Breeding between closely related individual organisms within a genetically heterogeneous species.

incidence Frequency with which a condition or a disease occurs or is diagnosed in a population.

incomplete penetrance Situation in which a dominant allele fails to affect phenotype because of the actions of other genes present in an organism’s genome. *See also* **penetrance**.

indel Insertion or deletion mutation.

indication A clinically observed trait or property that represents a valid reason for the making of a certain diagnosis or use of a certain therapy.

indolent Referring to a tumor that is apparently nongrowing or growing at a very slow rate.

inflammasome Multi-subunit complex that assembles in the cytosol in response to detection of pathogens or danger-associated cellular changes and proceeds to trigger cell death via caspase activation. *See also* **caspase**.

inflammation A process in which certain cellular components of the immune system are involved in the remodeling of a tissue in response to wounding, irritation, or infection.

inhibitor of apoptosis Cellular protein that blocks apoptosis by sequestering caspases.

initiation (1) Process of changing a cell, usually in a stable, cell-heritable fashion, so that it and its descendants are able to respond subsequently to the stimulatory actions of a tumor-promoting agent. (2) Such a process, with the implication that the change involves a mutation. (3) The first step in multi-step tumorigenesis. *See also* **promotion**.

initiator Agent that triggers the first step in multi-step tumorigenesis. *See also* **initiation**.

initiator caspases A family of proteases (including caspase 2, 8, 9, and 10) that become activated by upstream activating signals in the apoptotic pathway and functions to activate other downstream members of the caspase family (so-called executioner caspases), which proteolytically cleave a number of cellular target proteins. *See also* **caspase**.

innate Referring to an entity or process that is inborn and therefore does not require specific experience or provocation in order to arise.

innate immune response An immune system response toward an antigen or a cell that occurs in the absence of prior exposure of an organism to this particular antigen or cell. *See also* **adaptive immune response**.

innervated Referring to a tissue that is penetrated by components of the nervous system, specifically neurons and their axons.

inoculum Inoculated material.

inoperable A tumor or disease condition that cannot be treated surgically because of its anatomical location or other property. *See also* **operable**.

inositol A polyalcohol configured as a six-membered ring that has a chemical composition similar to that of hexose and is generated by reduction of the hexose aldehyde group to an alcohol.

insertional mutagenesis Alteration of a gene and its function through the integration of a retroviral provirus or transposon into the gene itself or a closely linked chromosomal site.

integrase An enzyme that is specialized to integrate an episomal DNA, such as a retroviral DNA genome, into host-cell chromosomal DNA. *See also* **integration, episome**.

integration Insertion of a fragment of foreign double-stranded DNA (e.g., the DNA genome of an infecting virus) into chromosomal DNA so that the foreign DNA becomes covalently linked to the chromosomal DNA segments flanking it on both sides and can be replicated together with the flanking DNA during subsequent rounds of cell growth and division.

integrin A heterodimeric cell surface receptor that binds components of the extracellular matrix and transmits information about this binding to the cell interior; the cytoplasmic domain of an integrin may also be coupled with components of the cytoskeleton, thereby linking the extracellular matrix to the cytoskeleton.

interactome (1) The collection of all protein–protein interactions that operate within a cell. (2) The subset of these that can be determined

experimentally.

intercalation Insertion of one molecule between two other molecules; intercalation in DNA involves insertion of a planar hydrophobic molecule between two adjacent base pairs.

interferon A member of one of three classes of secreted signaling cytokines that participate in activation of various type of immune responses.

intergenic Referring to genomic sequences located between identified genes. *Compare* **intragenic**.

interleukin A secreted growth and differentiation factor that stimulates various cellular components of the immune system.

intermediary metabolism The collection of biochemical reactions within a cell that allow the interconversion of various molecular species into one another, involving both anabolic and catabolic reactions. *See* **anabolic, catabolic**.

internalization Process by which proteins and other molecules are imported into a body, usually referring to importation of molecules into cells.

International Cancer Genome Consortium A multi-national effort to characterize the genetic changes in the genomes of multiple types of human cancer including multiple cases of specific cancer types. *See also* **The Cancer Genome Atlas**; **Sanger Cancer Genome Project.**

interphase The portion of the cell cycle outside of M phase.

interstitial (n. pl., **interstices**) (1) Referring to the space between an array of objects. (2) The space within a tissue that lies between cells.

interstitial deletion Genetic alteration, often observed through analysis of karyotype, that causes deletion of an internal segment of a chromosomal arm.

interstitial matrix Portion of the extracellular matrix that resides between cells and is not a component of the basement membrane.

intracrine A mode of signaling in which a receptor and its bound ligand interact entirely within a cell to release signals, often anticipating or following a similar interaction occurring in the extracellular space. *Compare* **autocrine**, **endocrine**, **exocrine**, **juxtacrine**, **paracrine**.

intraepithelial (1) Referring to a change or an attribute confined to the epithelial cell layer. (2) Referring to a neoplasia that remains on the epithelial side of a basement membrane.

intragenic Process, event, or DNA sequence occurring within the genomic boundaries of a gene. *Compare* **intergenic**.

intravasation Process of invading into a blood or lymphatic vessel from the surrounding tissue. *See also* **extravasation**.

intravital Referring to a process that occurs in living tissue, such as imaging a process as it occurs in living tissue.

intrinsic resistance Referring to the resistance to therapy of a tumor that appears to have existed prior to the application of that therapy, *also termed* **primary resistance**. *Compare* **acquired resistance**.

intron Portion of a primary RNA transcript that is deleted during the process of splicing. *See also* **exon**.

invadopodium (pl., **-ia**) An organized structure on the surface of a cell in which plasma membrane–bound proteases degrade adjacent extracellular matrix, apparently to enable subsequent invasion by the cell as a whole. *Sometimes termed* **podosome**.

invagination Process by which planar structure, such as a membrane, is folded back on itself to generate a cavity or pouch.

invasion (1) Process by which cancer cells or groups thereof move from a primary tumor into adjacent normal tissue. (2) In the case of carcinomas, a

movement that involves breaching of the basement membrane.

invasion–metastasis cascade A succession of steps that enables primary tumor cells to spawn metastases, doing so via local invasion, intravasation into blood or lymphatic vessels, dissemination to distant tissues, extravasation into the parenchyma of those tissues, formation of micrometastases, and ultimately colonization leading to the formation of macroscopic metastases.

invasive (1) Referring to the increased aggressiveness of a tumor or its associated cells. (2) Referring to a procedure that involves the insertion of medical instruments into the body of a patient. *See also* **invasion**.

involution Regression or disappearance of a tissue, notably, the regression of the mammary epithelium upon weaning.

ionizing radiation A type of high-energy radiation that has enough energy to remove an electron from an atom or molecule, causing it to become ionized.

ischemia State within a tissue caused by inadequate access to circulating blood, resulting in hypoxia, decreased pH, and inadequate supply of nutrients.

isochromosome A chromosome in which one of the two chromosomal arms has been lost and replaced by a duplicated copy of the surviving arm.

isoelectric point The pH value at which a molecule, such as a protein, exhibits no net charge.

isoform Protein that is functionally and structurally similar but not identical to another protein. Multiple distinct isoforms of a protein are usually encoded either by a single gene (via alternative splicing of a pre-mRNA) or by closely related paralogous genes. *See* **paralog**.

isopycnic A form of centrifugation in which a medium or solution composed of components of different densities is established within a centrifuge tube in a continuous gradient of densities from most dense

solution at the bottom to least dense at the top; during centrifugation, analyte molecules, multi-subunit complexes, or organelles of a specific density will, at equilibrium, settle into a zone within the centrifuge tube that is equivalent to their own density, enabling the resolution of analytes of different densities.

junk DNA Genomic DNA that cannot be associated with any biological function.

juxtacrine Type of cell–cell signaling in which the signal-emitting cell must be directly apposed to the signal-receiving cell in order for the signal to be properly transmitted. *Compare* **autocrine**, **endocrine**, **exocrine**, **intracrine**, **paracrine**.

juxtamembrane Located immediately adjacent to a membrane.

Kaplan–Meier plot A convention for graphing various clinical observations in which the percentage of surviving patients (or another clinical parameter such as disease-free or progression-free survival) is plotted on the ordinate (*y*-axis), while the time course after initial diagnosis or treatment is plotted (usually in increments of months or years) on the abscissa (*x*-axis).

kataegis Localized areas of point mutations arising near sites of chromothripsis and affecting preferentially cytidine and guanine nucleotides. *See* **chromothripsis**.

karyotype (1) The array of chromosomes carried by a cell, as determined by detailed microscopic examination of these chromosomes usually performed with condensed chromosomes at metaphase. (2) Images of the metaphase chromosomes of a cell arrayed systematically by homologous pairs from the largest to the smallest pair.

karyotypic Referring to the array of chromosomes of a cell that can be visualized by microscopy.

keratin (1) Protein component of the intermediate filaments forming the cytoskeleton of epithelial cells; *also termed* **cytokeratin**. (2) Extracellular

protein forming hair, nails, and feathers left behind and deposited after keratin-forming cells die.

keratinocyte Epithelial cell type found in a variety of epithelial tissues, notably the skin. These cells are named after the cytokeratins that they express, which form key components of the cytoskeleton of these cells. *See also* **cytokeratin.**

keratosis A benign lesion of the keratinocyte lineage in the skin usually caused by exposure to ultraviolet solar radiation.

Ki-67 A nuclear protein that serves as a marker of actively proliferating cells and is expressed in all phases of the active cell cycle.

kinase Enzyme that removes the γ phosphate from ATP and covalently attaches the phosphate moiety to substrate molecules, often but not exclusively proteins.

kinetochore Nucleoprotein complex that is associated with the centromeric DNA of a chromosome and is responsible during mitosis or meiosis for forming physical connections between the chromosome and the microtubules of the spindle fibers.

kinome The complete repertoire of kinases encoded by a genome, such as the human genome.

knock-down Procedure whereby the expression of a gene is reduced through the introduction into a cell of an inhibitory molecule such as an shRNA or siRNA that interferes with expression of its cognate mRNA.

knock-in A targeted mutation achieved through the homologous recombination of an experimentally introduced, cloned DNA fragment containing, in part, sequences of the targeted gene; the resulting integration of the introduced fragment into the genome of a cell usually results in the addition of novel sequences that affect the function of the targeted gene. *See also* **knock-out**.

knock-out (1) A targeted mutation that is achieved by a knock-in genetic strategy that results in insertion of a genetically defective copy of a gene or portion of a gene into the homologous gene sequence residing in the genome of a cell or organism. (2) A targeted mutation that is achieved by introduction of a CRISPR-Cas9 construct into a cell. *See also* **knock-in, CRISPR-Cas9**.

Krebs cycle *See* **tricarboxylic acid cycle**.

labile Highly susceptible or vulnerable to being changed, including suffering inactivation or destruction.

lamellipodium (pl., **-ia**) A broad, sheetlike ruffle extending from the plasma membrane into the extracellular space that is typically found at the leading edge of a motile cell.

lamin A fibrillar protein component of the nuclear membrane.

laminin A fibrillar protein component of the basement membrane.

laser capture microdissection Procedure in which a laser beam is used to delineate a patch of cells away from other cells present in a tissue section mounted on a microscope slide; the cells forming the patch are subsequently selectively removed for further analysis.

latency The time period that defines the delay before a process reaches completion and becomes manifest or apparent.

latent An entity or process that is not readily detectable or apparent.

lead-time bias A bias (e.g., in measurement of patient survival time) created when a disease condition is diagnosed at an earlier stage of its natural multi-step progression schedule because newly developed and more sensitive or effective diagnostic techniques have been deployed; resulting lead-time biases can lead to the impression that the temporal course of disease has been increased, whereas disease progression is only being monitored starting at an earlier step of the naturally occurring process.

leiomyoma Benign tumor of the mesenchymal cells forming the wall of the uterus.

leukapheresis Procedure whereby leukocytes are prepared *ex vivo* from drawn blood prior to returning the remaining portions of the blood to the donor or to another recipient.

leukemia Malignancy of any of a variety of hematopoietic cell types, including the lineages leading to lymphocytes and granulocytes, in which the tumor cells are nonpigmented and dispersed throughout the circulation. *Compare* **lymphoma**.

leukemogenesis (adj., **-genic**) Process that creates a leukemia.

leukocyte A nonpigmented white blood cell such as a lymphocyte, monocyte, macrophage, neutrophil, or mast cell.

leukosis A leukemia-like disease of chickens.

library (1) A collection of DNA clones derived from a cell's or an organism's genome or from cDNAs prepared from its expressed mRNAs, in which each component clone ideally derives from a distinct gene in this genome. (2) A collection of chemical compounds such as those synthesized because of their possible therapeutic utility.

ligand Molecule that binds specifically to a receptor and thereby activates its signaling powers. *See also* **receptor**.

ligase An enzyme that covalently joins two molecules together; in the context of DNA, ligases join the 3′ end of one ssDNA to the 5′ end of another other via a phosphodiester linkage.

light chain Smaller of the two polypeptide chains that assemble to form immunoglobulins and related proteins. *Compare* **heavy chain**.

limiting dilution analysis Procedure in which the representation or percentage of a given cell type of interest within a larger, often heterogeneous cell population is gauged by diluting the sample of interest

and extrapolating from subsequent biological assays the concentration of the cell type of interest in the initial sample being analyzed.

lineage A continuous, linear succession of cells extending from an ancestral cell via multiple intervening generations to its most recent descendants.

liquid biopsy Sampling of the contents of the blood rather than the contents of a solid tissue such as a tumor.

lobe (1) A cluster of alveoli formed in the mammary gland. (2) One of seven major sectors of the lungs or four major sectors of the liver. *See* **alveoli**.

OceanofPDF.com

lobular Referring to a lobe.

locked nucleic acid A chemically synthesized oligonucleotide in which the ribose residues contain methylene bridges between their 2′ oxygens and 4′ carbons, which greatly increase the ability of the oligonucleotide as a whole to anneal to complementary sequences.

locus (1) Chromosome site that can be studied genetically and is presumed to be associated with a specific gene. (2) A genetic element that can be mapped by genetic analysis.

long terminal repeat A genetic segment that is present in two identical copies at the ends of a retroviral genome or transposon and carries a strong transcriptional promoter and sequences important for chromosomal integration.

longitudinal Referring to the repeated, successive monitoring of a single patient or a group of patients over an extended period of time.

loss-of-function Referring to a mutation that deprives a gene and/or its protein product of an existing function. *See also* **gain-of-function**.

loss of heterozygosity A genetic event in which one of two alleles at a heterozygous locus is lost; the lost allele may simply be discarded or be replaced with a duplicated copy of the surviving allele. *See also* **allelic deletion**.

low-grade Referring to a tumor that has progressed minimally and is still relatively benign. *Compare with* **high-grade**.

loxP A bacteriophage DNA sequence that, when present in pairs within a genome, can be acted upon by a Cre recombinase, resulting in a recombination event between the two loxP sequences and loss of the intervening DNA segment located between the two loxP sites. *See also* **Cre**.

luciferase An ATP-dependent light-emitting protein.

lumen (pl., **lumina**; adj., **luminal**) (1) The bore of a hollow, tubelike structure, such as the gut, a bronchiole in the lung, a blood vessel, or a duct in a secretory organ. (2) The enclosed cavity within a spherical structure, such as a membranous vesicle.

luminal Referring to a cavity in a tissue or the cells that line and face a lumen. See also **lumen**.

lumpectomy Surgical procedure in which a tumor is removed together with immediately surrounding normal tissue while leaving the bulk of the affected organ intact; usually used in the context of breast cancer surgery.

lymph Interstitial fluid between cells that is drained via the lymph nodes to larger lymphatic vessels that eventually empty into the venous circulation.

lymph node Small kidney-shaped structure through which lymph passes and where antigens scavenged by antigen-presenting cells are presented to B and T lymphocytes.

lymphangiogenesis The process of forming new lymphatic vessels.

lymphatic Referring to vessels and nodes that drain interstitial fluid from tissues and eventually deposit this fluid in the venous circulation.

lymphedema Swelling of a tissue due to accumulation of interstitial fluid, which in turn is caused by failure of proper drainage via lymphatic ducts.

lymphocytes Class of leukocytes that mediate humoral or cellular immunity, encompassing B cells, T cells, and NK cells and derivatives thereof.

lymphoid (1) Referring to the lymphatic system and its associated organelles. (2) Referring to the lineage of hematopoietic cells that yields B and T lymphocytes as well as natural killer cells. *Compare* **myeloid**.

lymphokine A cytokine or growth factor specialized to attract and/or activate lymphocytes.

lymphoma Solid tumor of lymphoid cells. *Compare* **leukemia**.

lymphopenia Deficiency of lymphocytes in the circulation. *Also termed* **lymphocytopenia**.

lymphotropic Capable of infecting lymphocytes.

Lynch syndrome A form of familial colorectal cancer caused by inherited mutations in one of several mismatch repair genes; also known as hereditary non-polyposis colorectal cancer (HNPCC). Beyond colorectal cancer, individuals with Lynch syndrome are also at increased risk of developing brain, stomach, and endometrial cancer as well as other cancer types. *See also* **hereditary non-polyposis colorectal cancer**.

lysate Product of experimentally dissolving the structure of a tissue or a population of cells, usually generated in order to liberate the internal contents of the tissue or cells.

lysosome A cytoplasmic vesicle that contains in its lumen degradative enzymes in a solution of low pH, allowing it to degrade various molecules that are introduced into it; in addition, cells may sense nutrient availability by gauging the concentrations of certain amino acids in the lumina of their lysosomes.

lytic Dissolving a cell or tissue; often associated with the potent cytopathic effects of certain viruses on specific host cells.

lytic cycle Cycle of viral infection and replication that results ultimately in the death of the infected host cell.

M1 macrophage A subtype of macrophages that is associated with highly cytotoxic and phagocytic powers and can function to assist the immune attack on cancer cells. *Compare* **M2 macrophage**.

M2 macrophage A subtype of macrophages that releases immunosuppressive cytokines, notably IL-10 and TGF-β, and also favors tissue repair and regeneration. *Compare* **M1 macrophage**.

macrometastasis A metastatic tumor of a size that allows it to be detected by a variety of clinically used imaging procedures and thus does not require

microscopy for its detection. *See also* **micrometastasis**.

macronucleus Larger of the two nuclei in many ciliate cells, which carries multiple copies of each gene and is used for the production of mRNAs.

macrophage A phagocytic cell that either resides over extended periods of time within a tissue or arises within the tissue via the differentiation of recently arrived bone marrow–derived monocytes and proceeds to engulf and digest various infectious agents and cellular debris, often in order to present resulting oligopeptides to the adaptive immune system; additional normal functions include the release of angiogenic factors, mitogens, and proteases as part of a wound-healing program. *See also* **phagocytic**.

MAF transcription factors A family of bZip-containing transcription factors involved in regulating tissue-specific transcription programs.

maintenance methyltransferase An enzyme that attaches a methyl group to an unmethylated CpG that is complementary to an existing methylated CpG in a DNA double helix.

major histocompatibility antigen One of a group of cell-surface proteins that are responsible for the presentation of oligopeptide antigens derived from proteolysis of intracellular proteins to responding cells of the immune system. *See also* **histocompatibility antigen**.

malignant Describing a growth that shows evidence of being locally invasive and possibly even metastatic.

malignant peripheral nerve sheath tumor A tumor, usually displaying mesenchymal traits, that often arises from a neurofibroma and derives from cells that form the cellular sheaths protecting peripheral nerves.

malpractice Clinical treatment that is not appropriate or optimal given existing standards of therapy and implying incompetence or willful neglect.

mammary Referring to the breast and its milk-producing glands.

mammogram The image produced by mammography. *See* **mammography**.

mammography A clinical procedure using X-rays to detect incipient breast cancers.

mass action Referring to a situation in which the rate of a chemical or biochemical reaction is governed by the concentration of one or more of its reactants.

mass cytometry Procedure whereby antigen-specific antibody molecules are coupled chemically (conjugated) to metal atoms of various isotopes followed by detection of resulting antigen-metal-antibody conjugates by mass spectrometry, enabling the simultaneous detection of several dozen antigens. *See also* **mass spectrometry**.

mass spectrometry Analytical procedure by which the mass-to-charge ratio of ions is measured. The presence of ions, which are generated by bombarding molecules with electrons, reveals the nature of the molecules being analyzed or fragments of such molecules, often leading to the identification of their chemical structure.

Masson's trichome stain A mixture of staining chemicals that, in one alternative version, stains collagen blue, muscles red, and nuclei dark brown.

mast cell Granulocyte of bone marrow origin that displays Fc receptors for binding IgE antibody molecules and undergoes IgE-mediated degranulation following encounter with antigens bound by the associated IgE molecules.

mastocytosis A benign excess of mast cells, which are normally involved in allergic responses, wound healing, and defense against pathogens. *See also* **mast cell**.

Matrigel A preparation of ECM components, largely of basement membrane origin, that is secreted by mouse sarcoma cells and is often used as a gelatinous matrix in which to suspend cells in three-dimensional culture.

matrisome The collection of molecular species that together form the extracellular matrix of a tissue or of cultured cells.

matrix metalloproteinases Secreted proteases that employ zinc ions in their catalytic sites and degrade extracellular proteins, largely components of the extracellular matrix.

maximum tolerated dose The dosage of an administered drug above which a patient suffers unacceptable levels of toxic side effects.

mechanotransduction Process by which a cell senses mechanical stimuli, such as tension in the adjacent extracellular matrix, and converts this physical information into intracellular biochemical signals.

median The numerical value of a measurement that resides halfway through a list of such measurements, the latter arrayed in an order of increasing or decreasing value.

medical Referring to the use of drugs, rather than surgery, to treat disease.

medical oncology The practice of treating cancer with drugs. *See also* **surgical oncology**, **radiation oncology**.

medium The fluid in which cells are propagated *in vitro. See also* **tissue culture**.

medulloblastoma Tumor of the primitive precursors of neurons in the cerebellum.

megakaryocyte Large cell of the hematopoietic system that produces platelets by pinching off fragments of its cytoplasm.

melanin A brown-black or red-brown pigment that is synthesized by melanocytes and, in the skin, transferred to basal keratinocytes, thereby creating pigmentation of the skin; alternatively, pigment is transferred to cells within the iris of the eye.

melanocyte Cell of neural crest origin that creates pigmentation of the skin and iris.

melanoma Tumor arising from the melanocytes present as the pigmented cells of the skin, iris, and retinal pigmented epithelium.

melanosome Melanin-containing body in the cytoplasm of a melanocyte that is transferred to a keratinocyte or cells of the iris in order to impart pigmentation to the latter.

membrane attack complex The complex of multiple proteins including cell surface–bound antibody molecules and complement proteins that can introduce pores in the nearby plasma membrane, thereby killing an involved cell.

memory *See* **immunological memory**.

menarche Timing in life of the first menstrual cycle. *See also* **menopause**.

menopause Time in life when menstrual cycles halt. *See also* **menarche**.

merotely Condition established during the prophase of mitosis when a single kinetochore becomes linked simultaneously to two opposing spindle fibers.

mesenchymal (1) Referring to tissue composed of cells of mesodermal origin, including fibroblasts, smooth muscle cells, endothelial cells, and adipocytes. (2) Referring to an individual cell type belonging to this class of cells. (3) Referring to a phenotypic state associated with mesenchymal markers and created by the epithelial–mesenchymal transition cell-biological program. *See* **epithelial–mesenchymal transition**.

mesenchymal–epithelial transition The reversal of the epithelial–mesenchymal transition program that converts phenotypically more-mesenchymal cells into more-epithelial derivatives. *Compare* **epithelial–mesenchymal transition**.

mesenchymal stem cell An oligopotent mesenchymal cell, often of bone marrow origin, that can be recruited to various tissues in which it can differentiate into chondrocytes, osteoblasts, adipocytes, and possibly other mesenchymal cell types.

mesoderm Middle layer of cells in an early chordate embryo lying between the ectoderm and endoderm, which is the precursor of mesenchymal tissues, including connective tissues and the hematopoietic system. *See also* mesenchymal.

mesothelioma Tumor of the epithelial membranes lining the lungs, peritoneal cavity, and heart.

messenger RNA (mRNA) The transcript of a gene that has been processed by splicing and exported to the cytoplasm where it serves as the template for protein synthesis conducted by ribosomes.

meta-analysis Statistical procedure for pooling and integrating the results of a number of independent experimental, clinical, or epidemiologic studies in order to generate a larger data set and greater statistical significance than is afforded by the data of only a single study.

metabolite Chemical species resulting from the metabolic conversion by enzymes of a precursor chemical species.

metalloproteinase A protease that contains a metal atom, usually zinc, in its catalytic site.

metaphase Second major phase of mitosis, during which chromosomes complete condensation and attach to the mitotic spindle after the nuclear membrane disappears; chromosomes are now readily observed in the light microscope following appropriate staining.

metaphase plate A plane or region that is approximately equidistant from the two poles of a dividing cell at which chromosomes align prior to the anaphase portion of the cell cycle.

metaphyta Plants composed of many cells.

metaplasia Replacement within a tissue of cells of one differentiation lineage by cells belonging to another lineage.

metastable State of a cell or process that appears over a period of time to be stable and unchanging but can in fact be changed by various signals or perturbants.

metastasis (pl., **-es**; adj., **metastatic**; v. **metastasize**) A neoplastic growth forming at one site in the body, the cells of which derive from a malignancy located elsewhere in the body, such as the site of primary tumor formation. (2) The process leading to the formation of metastases. *See also* **primary tumor**.

metastatic colonization The phenomenon in which disseminated tumor cells forming micrometastases succeed in spawning macroscopic metastases.

metastatic inefficiency Phenomenon in which only a minute portion of disseminated tumor cells succeed in spawning macroscopic metastases.

metastatic shower Clinical observation of an apparent synchronous formation of multiple new metastases at multiple sites of metastatic dissemination.

metastatic tropism The observed tendency of cancer cells from one specific primary tumor type to colonize preferentially one target organ or another.

metazoan Referring to animals composed of many cells. *Compare* **protozoan**.

methylator phenotype Tendency of the DNA methylation apparatus in a cell to drive excessive CpG methylation, leading to the hypermethylated state of its genome.

methyltransferase An enzyme that attaches methyl groups covalently to substrates, such as the cytosine bases of DNA or lysine residues of histones.

MHC class I A class of cell surface proteins that is specialized to acquire (during its maturation within the endoplasmic reticulum) oligopeptide fragments of its own intracellular proteins and thereafter present these

fragments on the cell surface where they may be recognized by components of the adaptive immune system such as CD8+ lymphocytes. *Compare* **MHC class II**.

MHC class II A class of cell surface proteins that is specialized to acquire (during its maturation within the endoplasmic reticulum) oligopeptide fragments of acquired phagocytosed cells or particles and thereafter present these fragments on the cell surface where they may be recognized by components of the adaptive immune system such as CD4+ lymphocytes. *Compare* **MHC class I**.

microarray A collection of sequence-specific DNA probes that are attached at specific sites to a solid substrate, such as a glass microscope slide; these probes may derive from specific genes scattered throughout a cell genome or from a particular subset of chosen genes. *See also* **DNA chip**.

microbiome The collection of microbes, largely bacteria, that exist naturally as commensal organisms in normal organs, such as the gastrointestional tract and the skin; each of these and other tissues carries its own spectrum of microbes and thus its own microbiome.

microembolus (pl., **microemboli**) Small body formed from cells or products of the clotting machinery that travels through the circulation and may be trapped in small vessels, often blocking further circulation through these vessels. *See also* **embolus**.

microenvironment (1) The biological environment within a tissue that is created by nearby cells that influence the behavior of a cell of interest. (2) In a tumor, the environment that is generated by the recruited stromal cells that are closely apposed to the neoplastic cells such as carcinoma cells.

micrometastasis A single cell or small clump of disseminated cancer cells that can only be visualized using one or another form of microscopy. *See also* **macrometastasis**.

micronucleus (1) A small fragment of a nucleus that has its own nuclear membrane and results from certain aberrations in cell division or from damage inflicted on a cell; micronuclei often carry only a single

chromosome and arise when this chromosome fails to be incorporated into the previously formed mitotic spindle, thereby escaping inclusion in the normal karyotypic array of a daughter cell. (2) Smaller of the two nuclei in many ciliate cells, which is used to carry and transmit the ciliate genome to progeny cells.

microRNA Endogenously synthesized RNA transcribed by RNA polymerase II and processed into 21- to 23-nt-long ssRNA that interferes with translation of an mRNA or causes its degradation, depending on the degree of complementarity with the mRNA.

microsatellite A DNA relatively short oligonucleotide segment of simple sequence that resides within a cell genome and is repeated hundreds, even thousands of times in this genome, often at sites scattered though this genome. *See also* **satellite**.

microsatellite instability A condition caused by mutations in genes involved in DNA mismatch repair that is manifested when microsatellite sequences undergo frequent expansion or shrinkage in length. *See also* **microsatellite**, **mismatch repair**.

microthrombus *See* **thrombus**, **embolus**.

mimetic An agent, such as a protein or chemical, that imitates or functionally mimics another agent.

minimal residual disease Following treatment of diagnosed tumors, the persistence of derived cancer cells that are undetectable by clinical or radiological measurements but nevertheless persist as potential sources of eventual clinical relapses.

mismatch repair Class of DNA repair processes that depend on proofreading a recently synthesized segment of DNA and removing any misincorporated bases that may have escaped previous correction by DNA polymerase-associated proofreading functions. Defects in mismatch repair lead to microsatellite instability. *See also* **microsatellite instability**, **proofreading.**

mis-segregation The failure to properly segregate chromosomes during mitosis or meiosis.

missense codon A triplet codon in the genetic code, often created by a point mutation, that specifies an amino acid residue different from that specified by the codon that it replaces. *See also* **nonsense codon**.

missense mutation Point mutation causing an amino acid substitution. *See* **missense codon**.

mitogen (adj., **-genic**) An agent that provokes cell proliferation.

mitosis (1) Nuclear division, composed of the four steps of prophase, metaphase, anaphase, and telophase, the last including cytokinesis. (2) Process by which a single cell separates its complement of chromosomes into two equal sets in preparation for the division of the cell into two daughter cells achieved by cytokinesis.

mitotic catastrophe Process by which unrepaired damage to DNA or chromosomes or mis-segregation of chromosomes causes cells to enter into M phase and die there through non-apoptotic mechanisms because of an inability to properly complete the critical final steps of mitosis.

mitotic recombination Recombination between homologous chromosomal arms occurring during somatic cell proliferation, often during the G2 phase of the cell cycle (rather than during mitosis).

mitotic spindle The complex array of microtubules that is responsible for separating the two sets of chromatids during the anaphase of mitosis.

molecular chaperone A protein that functions to facilitate the proper folding of unfolded or misfolded proteins, doing so without making or breaking covalent bonds.

monoallelic Referring to a state in which only one of the two copies of a gene is expressed or exerts effects on phenotype. *See also* **biallelic**.

monoclonal Describing a population of cells, all of which derive by direct descent from a single common ancestral cell. *See also* **oligoclonal**, **polyclonal**.

monoclonal antibody An antibody that is made via secretion by a population of cells that has been produced through the immortalization of a single antibody-producing plasma cell and subsequent clonal expansion of its descendants, so that all antibody molecules in a preparation are biochemically identical to one another and show identical antigen specificity. *See also* **hybridoma**.

monocyte Phagocytic leukocyte of bone marrow origin that circulates briefly in the blood before migrating into tissues, where it can differentiate into macrophages, osteoclasts, dendritic cells, Langerhans cells, and possibly other phagocytic cell types.

monogenic Referring to a phenotype or disease condition that can be traced to the actions of a single gene and its alleles. *See also* **polygenic**.

monolayer A population of cells growing *in vitro* as a layer one cell thick.

monomer Molecule composed of a single unit or a single subunit of a chemical entity that is capable of forming higher–molecular-weight polymeric structures by association with or covalent linkage to other identical or similar units.

monotherapy A therapy in which only a single drug or treatment is used at one time.

monozygotic Referring to two or more organisms derived from a single fertilized egg, thereby referring to identical twins, triplets, or multiple births involving higher numbers of genetically identical newborns.

morbidity The existence of a medical condition or disease.

morphogen Low–molecular-weight substance that induces cells to assemble and participate in the construction of a tissue of a certain shape and form.

morphogenesis Process whereby shape is created, usually referring to the creation of shape of various tissue and organ structures during embryonic development.

morphology Shape and form of a cell, tissue, or organism.

mortal Referring to a cell population having limited proliferative capacity. *Compare* **immortalization**.

mortality The rate or frequency of death from a particular disease condition.

motility (adj., **motile**) Tendency for movement, such as that of individual cells, from one location to another.

motogenic Referring to an agent or signal that stimulates cell movement or motility.

mTOR Serine/threonine kinase that forms the catalytic core of the mTORC1 and mTORC2 complexes; by responding to nutrient availability, mTORC1 acts as the central regulator of cell growth, biosynthesis, and autophagy.

mucin Member of a family of heavily glycosylated glycoproteins that are secreted by luminal cells in a variety of epithelial tissues and form gel-like aggregates in order to lubricate or erect barriers to protect the luminal and underlying epithelial cell layers.

mucosa Epithelial cell layer that secretes a mucus-like substance that forms a protective layer above the secreting cells.

multi-drug resistance Development by cancer cells under treatment of concomitant resistance to multiple chemically distinct species of therapeutic drugs.

multi-drug transporter Molecular pump embedded in the plasma membrane of a cell that is capable of exporting multiple distinct molecular

species including drug molecules from the cell. *See also* **multi-drug resistance**.

multimeric. Referring to a complex of multiple subunits. *See also* **monomer**, **dimer**, **trimer**, **tetramer**.

multiparous Referring to a woman who has given birth multiple times.

multiple myeloma *See* **myeloma**.

multiplicity of infection In virology, the ratio of number of infectious particles to the number of infectable cells.

multipotent Referring to the ability of a stem cell to differentiate into multiple distinct cell types. *See also* **totipotent**, **pluripotent**.

mural Referring to the outer cell layers of blood vessels, which are composed of pericytes and smooth muscle cells and surround the luminal endothelial cells.

murine Referring to the subgroup of rodents that includes mice and rats.

muscularis propria Layer of muscles immediately underlying the submucosal layer in the gastrointestinal tract.

mutability The susceptibility of a cell and its genome to alteration via mutation.

mutable Referring to an entity that is subject to change, notably a genome subject to genetic mutation.

mutagen (adj., **-genic**) An agent that creates a mutation. *See also* **genotoxic**.

mutagenicity The property of being mutagenic.

mutation Change in the genotype of a virus or cell that involves an alteration in the nucleotide sequence of its genome, in the arrangement of a segment within a chromosome, in the number of copies of a segment, in the

physical structure of a chromosome, or in the number of copies of a structurally normal chromosome.

mutational burden *See* **tumor mutational burden**.

mutator phenotype Cell state in which defects in DNA repair or mutagen detoxification lead to elevated numbers of mutations sustained per cell generation.

myelin Substance composed of lipid and protein that is applied around axons by Schwann cells and oligodendrocytes in order provide electrical insulation, thereby facilitating rapid signal conduction. *See also* **Schwann cells**.

myelo- Prefix referring to bone marrow or an entity of bone marrow origin.

myeloablation Clinical procedure involving the elimination of the hematopoietic system, including its cellular components residing in the bone marrow, usually achieved through the application of a toxic drug or whole-body radiation.

myelocytomatosis A malignancy of avian bone marrow cells.

myelodysplasia Condition in which incompletely differentiated cells of one or another myeloid lineage accumulate in the blood, often accompanied by a reduction in the concentration within the circulation of properly differentiated cells of bone marrow origin.

myelodysplastic syndrome Hyperproliferative condition of cells of the myeloid lineage in the bone marrow which often progresses to acute myelogenous leukemia.

myelogenous Originating in the bone marrow; *also termed* **myelocytic**. *See also* **myeloid**.

myeloid (1) Referring to the lineages of hematopoietic cells that yield cells that are not lymphocytes and includes erythrocytes, platelets, granulocytes, monocytes, mast cells, and their derivatives. (2) Pertaining to or resembling

bone marrow; often used as a synonym for myelogenous. *Compare* **lymphoid**.

myeloid derived suppressor cell Relatively undifferentiated cell of myeloid origin, deriving from cells of the granulocytic or monocytic lineages, that exerts potent immunosuppressive functions on other immune cells of both the innate and adaptive arms of the immune system.

myeloma A malignancy of the antibody-producing cells of the bone marrow, often called multiple myeloma to indicate the large number of osteolytic lesions that are encountered in patients with advanced disease.

myeloproliferative Referring to excessive proliferation and resulting elevated levels of one of the several cell types generated by the myeloid branch of the hematopoietic system.

myoblasts The undifferentiated precursors of the myocytes present in differentiated muscle. *See also* **myocytes**.

myocytes The individual contractile cells that assemble to form functional muscles. *See also* **myoblasts**.

myofibroblast A type of fibroblast that is normally involved in wound healing and inflammation and is often defined by its expression of α-smooth muscle actin which, together with myosin, imparts to it contractile powers.

N-terminus (adj., **-al**) End of a protein chain at which synthesis is initiated. *See also* **C-terminus**.

naive Referring to immune lymphocytes that have not experienced contact with cognate antigens and have not, as a consequence, undergone the biological activation associated with such contact.

nascent Referring to an entity, such as a molecule, that is in the course of being formed or synthesized.

natal Referring to birth. *See also* **prenatal**.

natural killer cells A type of lymphocyte whose ability to attack target cells is not dependent on any form of adaptive immunity. *See also* **innate immune response**.

natural product A chemical species that is a product of the natural metabolism of an organism, such as a bacterium, fungus, or plant.

NCI-60 cell lines (often **NCI-60**) The collection of 60 human cancer cell lines prepared from nine commonly occurring tumor types and provided by the U.S. National Cancer Institute that is often used to gauge the responsiveness of different types of cancer cells to therapeutic agents under development.

necroptosis A programmed form of necrosis that leads to cell death and the release of cellular debris that may persist and trigger local tissue inflammation. *See also* **apoptosis**, **ferroptosis**, **pyroptosis**.

necrosis A non-programmed form of cell death triggered by the collapse of cellular energy production, involving the breakdown of a cell's constituents through steps that are distinct from those in the neocroptosis and apoptotic death programs. *See* **necroptosis**, **apoptosis**.

necrotic Referring to a region of a normal or neoplastic tissue in which the cells have died.

negative feedback A regulatory process whereby a stimulatory signal upstream in a signaling pathway activates a downstream target that proceeds to inhibit the source of the initial upstream signal, thereby reducing further overall signaling. *See also* **positive feedback**.

neoadjuvant Referring to a treatment that is undertaken before the main therapy is applied, e.g., to reduce tumor size before surgery. *See also* **adjuvant**.

neoangiogenesis *See* **angiogenesis**.

neoantigen An antigen that is newly formed by tumor cells, usually during the course of tumor development, and is created by somatic mutations

affecting the reading frames of cellular mRNAs.

neomorphic Referring to a mutation that confers a novel function on a gene and encoded protein.

neoplasia (adj., **-plastic**) (1) The state of cancerous growth. (2) Benign or malignant tumor composed of cells having an abnormal appearance and abnormal proliferation pattern.

neoplasm A tumor. *See also* **neoplasia**.

neovasculature Vasculature that is newly developed, often by a growing tumor. *See also* **vasculature**.

neural crest Dorsal region of the early chordate embryo that contains cells serving as precursors of various specialized tissue and cell types, including certain cells of the peripheral nervous system, bones of the face, melanocytes, and several types of neurosecretory cells.

neurite A thin provisional protrusion from the cell body of a neuron that has the potential to develop into a fully formed, functional axon. *See also* **axon**, **neuron**.

neuroblastoma Tumor of primitive neuronal precursor cells of the peripheral nervous system and adrenal medulla.

neuroectodermal Referring to the components of the nervous system, which derive from the embryonic ectoderm.

neuroendocrine Referring to a cell type that releases certain hormones in response to neuronal signals.

neurofibroma Benign tumor of cells forming the sheath around nerve axons.

neurofibrosarcoma Malignant tumor of cells forming the sheath around nerve axons.

neuron A nucleated cell in nervous tissue from which neurites and axons extend. *See* **axon**, **neurite**.

neuropeptide A small protein or oligopeptide that is produced by cleavage of a higher–molecular-weight precursor and is released by certain cells of the central nervous system and neuroendocrinal cells and that impinges upon and thereby signals to other cells inside and outside of the central nervous system.

neurosecretory Referring to a cell type that will secrete a substance, such as a hormone, in response to neuronal signals.

neurotrophic Referring to secreted factors that support the growth, survival, and differentiation of nervous tissue.

neutral mutation Change in DNA sequence that has no effect on phenotype, including mutations that have no effect on protein structure.

neutralization Inactivation of a biological activity, such as inactivation of viral infectivity by antibody molecules.

neutropenia Deficiency of neutrophils in the marrow and circulation.

neutrophil An abundant granulocyte in the circulation that expresses Fc receptors and is responsible for multiple functions, including recognizing and engulfing various types of infectious agents and participating in various types of inflammation.

neutrophilia A condition in which the concentration of neutrophils in the circulation is elevated above its normal value.

nevus (pl., **nevi**) A benign growth of melanocytes in the skin yielding moles or collections of pigmented cells that may, at low probability, progress into a melanoma.

next-generation sequencing A set of high-throughput methods used to determine a portion of the nucleotide sequence of DNA. These techniques utilize DNA sequencing technologies that are capable of determining

multiple DNA sequences in parallel. *Also called* massively parallel sequencing.

niche A functional locale that supports the survival and proliferation of specialized cells. Specific niches support the proliferation and survival of stem cells in normal tissues and, quite possibly, cancer stem cells in tumors.

NKG2D Receptor expressed by natural killer cells and other immunocytes that recognizes MHC-like molecules displayed by other cells undergoing various types of physiological stress and may trigger a cytolytic attack on such cells in response.

non-canonical Referring to a representation of an entity or process that differs from the most widely accepted, often initially established representation. *See also* **canonical**.

nondisjunction (1) Failure of two chromatids to separate from one another during mitosis or two homologous chromosomes to separate from one another during meiosis. (2) State created by this failure of separation.

nongenotoxic Incapable of damaging a genome. *See also* **genotoxic**.

nonhomologous end joining Type of DNA repair consisting of fusion of two dsDNA ends, in which the precise joining of the two ends is not informed or directed by sequences present in a normal sister chromatid or homologous chromosome.

nonhomologous recombination Process of recombination between two DNA molecules in which the two participating molecules do not share significant sequence identity. *Also called* **illegitimate recombination**.

noninvasive Referring to procedures that allow diagnosis or treatment without the need to enter the body with diagnostic instruments or surgery.

nonpermissive (1) Describing a physiological state that does not permit the survival and/or proliferation of a cell or infectious agent such as a temperature-sensitive virus. (2) Describing a type of host or host cell that does not permit cells or infectious agents to proliferate. *See* **permissive**.

non-self Constituent or agent in the body that is of foreign, non-native origin. *See also* **self**.

nonsense codon A triplet codon in the genetic code that specifies termination of the growing polypeptide chain; nonsense codons generated by point mutations within reading frames cause premature termination of translation and resulting formation of truncated proteins. *See also* **missense codon**.

nonsense mutation Mutation causing premature termination of a growing polypeptide chain. *See also* **nonsense codon**.

non-small-cell lung carcinoma Any of several types of lung cancers with the exception of small-cell lung carcinoma.

nonsynonymous A nucleotide mutation that alters the amino acid sequence of an encoded protein. Nonsynonymous mutations differ from synonymous mutations, which do not alter amino acid sequences of encoded proteins. *See also* **synonymous**.

normoxia A level of oxygen that corresponds to that normally experienced by cells in a specific tissue environment. *See also* **hypoxia**.

Northern blot Adaptation of the Southern blotting procedure in which RNA (rather than DNA) is resolved by gel electrophoresis and transferred to a filter that is subsequently incubated with a sequence-specific, radiolabeled DNA probe. *See also* **Southern blot**, **Western blot**.

nuclear magnetic resonance Analytical procedure for determining molecular structures and interactions in which molecules are placed under strong magnetic fields and the influence of radio frequency waves; the frequencies at which the atoms within a molecule resonate yields information on the molecular interactions of individual atoms and, in turn, the overall structure of a complex molecule.

nuclear receptor One of a family of nuclear DNA-binding proteins that bind lipid-soluble ligands and, in response, undergo a conformational shift

that enables them to directly control the transcription of genes to which they are bound.

nucleolus The organelle within the cell nucleus that is the site of ribosomal subunit biosynthesis.

nucleophilic Referring to a molecule that seeks out and reacts with electron-poor substrates. *Compare* **electrophilic**.

nucleoplasm The unstructured portion of the nucleus that does not include the nucleoli and chromosomes.

nucleosome Protein octamer, composed of two each of histones H2A, H2B, H3, and H4, around which DNA is wrapped in chromatin.

nucleotide-excision repair Type of DNA repair in which the initial step involves the excision of nucleotides (rather than bases). *Compare* **base-excision repair**.

null allele An allele of a gene that lacks all normal functions of the gene. *See also* **hypomorphic**.

nulliparous Referring to a female who has never given birth.

objective response Demonstration of clinical response to therapy as gauged by changes in progression-free survival, overall survival, time to progression, size of tumor, marked improvement in patient symptoms, or other measurable response to therapy.

obviate To render unnecessary.

occlude To block access to.

occult Hidden, inapparent.

ocular Referring to the eye.

off-target effects Effects of a therapeutic agent on molecules or cell types other than the intended targeted molecules or cell types.

Okazaki fragment A short DNA fragment of 150–200 nucleotides that enables lagging strand polymerization and is joined soon after its formation to adjacent Okazaki fragments by a DNA ligase.

oligoclonal Referring to a cell population that contains the descendants of a small number of founding cells. *See also* **polyclonal**, **monoclonal**.

oligomer A polymer of several monomeric subunits.

oligonucleotide A polymer composed of a relatively small number of nucleotides.

oligopeptide A short protein chain consisting of a relatively small number of amino acids.

oligopotent Referring to the ability of a less differentiated cell, such as a stem cell, to differentiate into two more distinct progeny.

-oma Denoting a benign or malignant growth.

-ome Suffix referring to the entire spectrum of a type of entity being expressed in a given cell or tissue, e.g., genome, proteome, (DNA) methylome, transcriptome, orfeome, matrisome or secretome.

ommatidium (pl., **-ia**) The individual compartment within the multi-compartment arthropod eye in which light is sensed.

oncofetal Referring to an antigen that is normally expressed transiently during embryonic development and is also expressed by some tumor cells.

oncogene (1) A cancer-inducing gene. (2) A gene that can transform cells from a normal to a neoplastic state.

oncogene addiction (1) The physiological state of a cancer cell in which it continues to be dependent for its proliferation or survival on the ongoing function of a certain oncogene, usually a mutant oncogene, often long after the oncogene has been acquired during the course of multi-step tumorigenesis. (2) More generally, ongoing dependence on any type of previously acquired genetic or epigenetic alteration.

oncogenic Referring to the ability to induce or cause cancer.

oncologist A physician who treats cancer, usually through medical rather than surgical means.

oncometabolite A chemical species that accumulates within cancer cells and contributes to their neoplastic transformation, e.g., 2-hydroxyglutarate.

oncomiR A microRNA associated with or causing cell transformation or contributing to tumor progression.

oncoprotein A protein specified by an oncogene that mediates its effects on cell physiology, often including neoplastic transformation.

ontogeny The developmental history of an individual organism.

open reading frame A sequence that encodes a continuous polypeptide segment, usually encompassing the entirety of the coding information of a gene.

operable Capable of being treated successfully by surgery. *See also* **inoperable**.

opportunistic A process, such as an infectious event, that exploits an environment that normally would be inhospitable to that process. An opportunistic infection by a virus occurs in host organisms that have compromised antiviral defense mechanisms.

opsonization Process of coating a cell, including a bacterial cell, with antibody molecules that recognize and bind cell surface antigens expressed by the cell; such binding often leads to the phagocytosis of the antibody-coated cell by phagocytes, such as macrophages, that display Fc receptors on their surface.

ordinate The vertical or *y*-axis of a Cartesian graph. *See also* **abscissa**.

orfeome The collection of many or all of the open reading frames expressed within a cell or cell type.

organelle A subcellular structure, such as a ribosome, mitochondrion, or Golgi apparatus.

organoid An experimentally created model of a normal adult tissue, usually generated through incubation of organ-specific stemlike cells suspended in a three-dimensional gelatinous matrix containing a cocktail of factors designed to induce a tissue-specific differentiation program in the organoid.

organotropism The tendency of cancer cells in a specific type of primary tumor to spawn metastases in a specific subset of normal tissues in the body.

organotypic Tending to reflect or recapitulate a state or condition mimicking the one operating within a specific organ or tissue.

origin of replication DNA segment that determines the site of initiation of replication in a chromosome, viral genome, or episome, often resulting in two diverging replication forks.

oropharynx (adj., **oropharyngeal**) The cavity extending from the back of the mouth down the respiratory tract to the larynx (voice box).

ortholog (*also* **orthologue**) A gene in one species that is the closest relative of a gene in another species, with the two genes arising from a common ancestral gene in a common ancestral species; usually orthologs represent direct counterparts of one another in the genomes of two species, often retaining very similar functions. *See also* **homolog**, **paralog**.

orthotopic Referring to an anatomically proper or native site. *See also* **ectopic**.

osteoblast Mesenchymal cell type related to fibroblasts that constructs mineralized bone through the deposition of a collagenous matrix and apatite crystals.

osteoblastic Referring to a class of bone lesions that involve localized increases in the amount of mineralized bone. *See also* **osteolytic**.

osteoclast Cell type of monocyte origin that functions to degrade and demineralize already-assembled bone.

osteoid The extracellular matrix that forms during bone formation prior to mineralization.

osteolytic Referring to a bone lesion that involves localized dissolution of mineralized bone usually driven by the localized actions of osteoclasts. *See also* **osteoblastic**.

osteotropism The trait of cells, notably metastasizing cancer cells, to migrate to and colonize the bone marrow.

outcomes research The practice of evaluating treatment protocols by comparing clinical outcomes achieved by several alternative protocols, usually in controlled clinical trials.

overall survival Proportion of patients who are still alive at a certain time following initiation of treatment, often measured after a certain interval, such as five years, after such treatment initiation. *See also* **progression-free survival**, **disease-free survival**.

overexpression Expression of an RNA or a protein at higher-than-normal levels.

oxidative phosphorylation The process of generating ATP from ADP driven by electron gradients in the mitochondrion.

p value Statistical parameter describing the probability that an event or quantity occurred simply by random chance.

Paneth cell Secretory cells that reside in the bottom of intestinal crypts and also help to create a stem-cell niche for adjacent intestinal stem cells. *See also* **niche**.

papilloma Benign, adenomatous proliferation of epithelial cells; term often used to describe benign lesions of the skin.

papovaviruses Class of viruses that includes SV40, polyomavirus, and papillomaviruses.

paracrine Referring to the signaling path of a hormone or factor that is released by one cell and acts on a nearby cell, ostensibly after transport through the interstitial fluid of a tissue. *Compare* **autocrine**, **endocrine, exocrine, intracrine**, **juxtacrine**.

parallel progression Process whereby cancer cells advance through multi-step tumor progression at sites distant from and independently of the primary tumor. *See also* **primary tumor**.

paralog (*also* **paralogue**) A gene or protein that is related to another gene or protein through evolution from a common ancestral precursor; paralogs usually arise via gene duplication followed by sequence divergence of the two resulting genes, often with the development of two distinct functions, with both resulting genes continuing to be present in the genome of a descendant organism. *See also* **homolog, ortholog**.

paraneoplastic Referring to a biological effect evoked in the body by a tumor at a site in the body that is located some distance from the tumor itself and is apparently not directly involved in the pathogenesis of the tumor.

parenchyma The portion of a tissue that lies outside the circulatory system and often is responsible for carrying out the specialized functions of the tissue.

parenteral Referring to a route of substance administration (usually injection) or infectious-agent transmission not involving the mouth or gastrointestinal tract.

parity (1) The condition of having given birth. (2) The number of times that a female has given birth.

parous Referring to a female who has given birth at least once.

partial response Halting of further tumor growth or a 50% or greater reduction in tumor mass following anti-cancer therapy. *See also* **complete response**.

passaging (1) Practice of transferring cells from one culture vessel to another, often performed because the cell population has filled up the first vessel. (2) Similarly, the transfer of tumor cells or infectious agents, notably viruses, from one host cell or organism to another. *See also* **serial passaging**.

passenger gene Gene altered by passenger mutation. *See* **passenger mutation**.

passenger mutation Mutation that confers no selective advantage on a cell carrying it but whose presence in a population of cells is increased because it resides in the same genome as other mutant alleles that do indeed confer advantage; sometimes termed bystander mutation. *Compare* **driver mutation**.

passive immunization Procedure in which the immune responses of an organism are supplemented or strengthened through the introduction of immunological agents, usually antibodies or immunocytes, of foreign origin.

pathogen Agent that causes disease, often as an infectious agent.

pathogenesis Process that leads to the creation of a disease state or diseased tissue.

pathological (1) Diseased or associated with a disease. (2) Referring to the study of a disease process, often at the level of light microscopy.

pathological complete response The response of a tumor to a therapy that involves the complete elimination of microscopically detectable remnants of a tumor under treatment. *See* **complete response**.

pathologist Physician who examines tissues microscopically to study and classify disease.

pathology (1) A disease or disease condition. (2) The science of analyzing a tissue by studying its microscopic structure. *See also* **histopathology**.

patient-derived xenograft A population of cancer cells that is derived by implanting fragments of patients' tumors directly into immunocompromised mouse hosts, thereby avoiding initial *ex vivo* propagation of tumor cells in tissue culture.

pausing *See* **polymerase pausing**.

pediatric Referring to an attribute or condition of children.

penetrance Extent to which an allele of a gene can or cannot influence phenotype, e.g., the likelihood that a germ-line allele will or will not induce a clinical phenotype in a carrier of this allele. *See also* **expressivity, incomplete penetrance**.

-penia Suffix denoting a deficiency or abnormally low levels of a substance or entity, usually detected in the circulation.

peptidase Peptide-cleaving enzyme.

perforin A protein made by cytotoxic immune cells and inserted by them into the plasma membrane of a targeted cell; once inserted, perforin molecules assemble to create a channel through the membrane that causes the death of the cell, often by allowing the introduction of pro-apoptotic proteins such as granzymes into the cell.

peri- Prefix implying surrounding or around.

pericytes Cells closely related to smooth muscle cells that surround capillaries and provide the capillary walls formed by endothelial cells with tensile strength and contractility; pericytes also provide trophic signals to nearby endothelial cells. *See also* **trophic**.

perineural invasion Invasion of cancer cells along tracts established by neurons and axons.

perineurial Referring to the fibroblast-like cells that wrap around and protect nerve axons.

perinuclear Surrounding or near to the cell nucleus.

peripheral neuropathy Damage to peripheral nerves, usually in the limbs, that affects muscle coordination or sensation and may even create sensed pain.

peripheral tolerance Process by which T cells recognizing self-antigens are eliminated or functionally inactivated in lymph nodes throughout the body rather than centrally in the thymus. *Compare* **central tolerance**.

peritoneal Referring to the cavity in the abdomen that is limited by an enclosing membrane and includes the lower gastrointestinal tract and associated organs, including pancreas and liver.

peritoneovenous shunt A tube that is inserted into the peritoneal space that allows the collection of cancer cells forming the ascites fluid in patients suffering high-grade cancers; the cancer cells, which enter through holes in the tube, are eventually emptied directly by the tube into the venous circulation, often via the vena cava.

permissive (1) Describing a physiological state that allows the survival and/or proliferation of a cell or infectious agent, such as a temperature-sensitive virus. (2) Describing a type of host or host cell that allows cells or infectious agents to proliferate. *See also* **nonpermissive**.

peroxidase An enzyme, often prepared from horseradish, that reduces peroxides and is often used in immunohistochemistry, when coupled to an antibody, to generate via oxidation products that exhibit a characteristic color.

peroxisome A cytoplasmic vesicular organelle that is involved in the oxidation of various substrates, notably lipids.

Peto's paradox The discrepancy, first noted by Richard Peto, that large bodied, long-lived organisms do not confront greater cancer incidence than

corresponding smaller, short-lived animals in spite of vast differences in cumulative cell divisions experienced during an average lifetime.

phage *See* **bacteriophage**.

phagocyte, (adj. **phagocytic**) Cell of the immune system—e.g., a macrophage or dendritic cell—that is specialized to engulf and destroy other cells, cellular fragments, and other debris.

phagocytosis Endocytotic process by which a cell, usually a component of the immune system, engulfs a particle (which may be another cell), internalizes this particle, and usually proceeds to degrade it by introducing it into lysosomes. *See also* **endocytosis**.

phagolysosomes Vesicular structure in the cytoplasm formed by the fusion of a phagosome with a lysosome. *See also* **phagosome**.

phagosome A vacuole or vesicle formed in the cytoplasm directly by the process of phagocytosis.

pharmacodynamics Time course of biological responses within a tissue or its cells that are induced by a drug, usually gauged at different times after initial administration.

pharmacokinetics Results of measurements gauging the rise and fall in the concentration of an administered drug in the body, usually measured in the plasma and gauged at different times after initial administration.

pharmacological Referring to the study and use of drugs, usually those of low molecular weight.

phase I A clinical trial with a relatively small group of patients that gauges the safety/tolerability of a new experimental drug as well as its pharmacokinetics and pharmacodynamics. *Compare* **phase II**, **phase III**.

phase II A clinical trial in a large group (e.g., hundreds) of patients in which the safety of a new drug is further examined after completion of a

phase I trial as well as its potential therapeutic efficacy, e.g., its ability to affect the growth of certain tumors. *Compare* **phase I**, **phase III**.

phase III A clinical trial in which very large numbers (e.g., hundreds to thousands) of patients are exposed to a new drug, given in a randomized fashion with placebo controls, and tested for its efficacy relative to existing approved therapeutic modalities, with the intent of demonstrating statistically significant clinical benefit, usually one greater than existing approved therapies. *Compare* **phase I**, **phase II**.

phasing The process controlling the precise positioning of DNA-bound nucleosomes relative to specific nucleotide sequence landmarks along the DNA.

phenocopy (1) A biological entity—cell, tissue, or organism—that replicates the phenotype of another entity even though the two entities may have distinct underlying genotypes or arise through distinct mechanisms. (2) To create a phenocopy. *See also* **phenotype**.

phenomenon (pl., **phenomena**) An observable process or entity.

phenotype (1) A measurable or observable trait of an organism. (2) The sum of all such traits of an organism.

pheochromocytoma Tumor of the neural crest-derived cells of the adrenal glands that secrete elevated levels of certain hormones through which they may instigate a number of abnormal clinical symptoms.

phosphatase An enzyme that removes phosphate groups from phosphorylated substrates, such as the phosphoamino acid residues in a protein or the phosphorylated inositol of a phospholipid.

phosphoprotein A protein to which one or more phosphate groups have been covalently attached, usually to threonine, serine, or tyrosine residues.

phosphoproteome A census of phosphoproteins, such as all those that can be shown to be present within a given cell.

phosphorylation Covalent attachment of a phosphate group to a substrate, often the side chain of an amino acid residue of a protein. *See also* **phosphoprotein**.

phylogeny The evolutionary history and development of a species.

physiological (1) Referring to the function of a biological system, such as a cell or organ. (2) Referring to the normal state of function of a biological system or process. *Also termed* **physiologic**.

physiology (1) Biological functioning of cells, tissues, organs, and organisms. (2) The study thereof.

phytochemical A chemical species produced by a plant as part of its normal metabolism.

pimonidazole 1-[(2-hydroxy-3-piperidinyl)propyl]-2- nitroimidazole hydrochloride, a chemical used to detect regions of hypoxia within a tissue.

pinocytosis Process similar to endocytosis in which a small volume of extracellular fluid together with its dissolved contents is internalized by the invagination of patches of plasma membrane, yielding cytoplasmic vesicles. *See also* **endocytosis**.

placebo A therapy or agent that is thought or known to be ineffective but is intended to deceive patients into believing that they are being treated with a therapy or agent that is or may be truly effective.

planar cell polarity Process by which the individual cells forming an epithelial cell sheet acquire a polarity, specifically along axes parallel to the plane of the sheet, and is coordinated with other cells in the plane of the sheet, resulting in an ordered, organized epithelium.

-plasia Suffix denoting a growth.

plasma The fluid component of blood that is left behind when its cellular components are removed, usually by centrifugation.

plasma cells Cells of the B-cell lineage that secrete antibodies into the blood plasma.

plasma membrane Lipid bilayer membrane that surrounds a eukaryotic cell and separates the aqueous environment of the cytoplasm from that of the extracellular space.

plasminogen The inactive pro-enzyme in the plasma that is converted into the active plasmin protease through proteolytic cleavage as part of the process of clotting.

plasticity Describing an ability to readily transit between alternative states, such as distinct phenotypic states.

pleiomorphic Referring to a population of cells in which individual cells exhibit diverse morphologies seen upon microscopic examination.

pleiotropy Ability of a gene or protein to concomitantly evoke multiple distinct downstream responses within a cell or organism.

pleura The membrane that covers the surface of the lungs and lines the inner wall of the chest. *See also* **pleural**.

pleural Referring to the spaces between the membrane covering the lungs and the wall of the chest and the underlying tissues covered by this membrane.

pleural effusion Accumulation of cancer cells and fluid in the space between the lungs and the surrounding pleural membrane.

plexiform Forming an interwoven network.

ploidy The number of haploid genome sets of chromosomes in a cell or organism, e.g., diploid, triploid, tetraploid.

pluripotent Referring to the ability of a stem cell to generate progeny that can participate in the formation of all of the tissues of an embryo except the extraembryonic membranes. *See also* **multipotent**, **totipotent**.

pneumocyte Epithelial cell lining the alveoli of the lungs that is responsible for gas exchange with the blood and the secretion of surfactant protein.

pocket protein Term referring to pRb and two related proteins, p107 and p130.

podosome *See* **invadopodium**.

-**poiesis** Suffix referring to the formation of a cell or tissue, often used to refer to the formation of various types of cells in the blood. *See* **hematopoiesis**.

point mutation Substitution of a single base for another in a DNA sequence.

polar Referring to a chemical compound that contains charged groups and is therefore hydrophilic.

polarity Phenomenon by which a cell can organize its cytoplasm, and therefore its general axis of orientation, into distinct regions, such as the behavior of epithelial cells forming a cell sheet and acquiring apical versus basal polarity or planar cell polarity. *See also* **apico–basal polarity**, **planar cell polarity**.

polyclonal Describing a population of cells that trace their origins to multiple founding ancestral cells. *See also* **monoclonal**, **oligoclonal**.

polycomb Group of multi-subunit protein complexes that remodel chromatin and place it in a transcriptionally repressed state. *See also* **polycomb domain**.

polycomb domain A region of chromatin that has been placed in a transcriptionally repressed state through the actions of polycomb complexes. *See also* **polycomb**.

polycyclic Referring to molecules with a structure that contains multiple covalently closed rings.

polycyclic aromatic hydrocarbon A hydrocarbon molecule that carries multiple benzene rings.

polycythemia Condition involving higher-than-normal levels of circulating red blood cells.

polygenic Referring to a phenotype or disease condition that is thought to be caused by or can be traced to the collaborative actions of multiple genes and their alleles. *See also* **monogenic**.

polykaryon Cell carrying multiple nuclei in a single cytoplasm.

polymer A molecule composed of a large number of monomeric subunits, usually joined covalently end-to-end in a linear array.

polymerase An enzyme that can join end-to-end multiple nucleotides, thereby assembling a DNA or an RNA molecule.

polymerase chain reaction Procedure by which large copy numbers of a double-strand DNA segment can be generated *in vitro* by repeated cycles of denaturation, followed by DNA replication that is enabled by the presence of short primers of the appropriate sequence at its ends; the DNA segment being copied may be a naturally existing DNA molecule, one generated by reverse transcription, or one arising from a chemically synthesized DNA molecule.

polymerase pausing The process in which an RNA polymerase, usually Pol II, initiates elongation of an RNA transcript and halts after producing 25–50 nucleotide-long transcripts until it is released from the pause site by various anti-pausing regulators and permitted to complete transcription of a gene.

polymorphism A variant genetic allele or phenotype that does not appear to be associated with any pathology and, by implication, is a reflection of normal intraspecies variability and thus normal function.

polyp A tumor, usually presumed to be premalignant, protruding into the lumen of an organ, such as gut or bladder, often equated with an adenoma.

See also **adenoma, polyposis**.

polypectomy Surgical removal of a (colonic) polyp.

polyploid Referring to a genome in which the entire haploid array of chromosomes is represented in copy numbers larger than two. *See also* **haploid**, **diploid**.

polyploidy The state of a karyotype that contains an array of chromosomes that exceeds the normal number.

polyposis Tendency to develop multiple preneoplastic polyps in the gut. *See also* **polyp**.

polyprotein Initial product of translation that is cleaved subsequently into multiple smaller proteins, each of which may then exhibit its own distinct function.

polyubiquitin Chain of covalently joined multiple ubiquitin subunits. *See also* **ubiquitin**.

polyvalent Having multiple distinct reactivities, such as multiple reactive chemical groups within a single molecule or multiple antigens administered together in a single vaccine.

pool A population or collection of similar entities, e.g., a gene pool or a pool of stem cells.

porcupine An *O*-acyltransferase enzyme that attaches lipid tails to Wnt proteins post-translationally, preparing them for secretion and signaling by binding cognate Frizzled receptors.

portal Referring to the properties of the vena porta and the veins that it drains, which convey venous blood directly from the pancreas, spleen, and intestine to the liver.

positive feedback A regulatory process whereby an upstream stimulatory signal provokes a downstream target that proceeds to sustain and/or amplify

signaling by the initial stimulatory signal. *See also* **feedforward**, **negative feedback**.

post mortem Referring to a biological process or medical analysis that occurs after death.

post-mitotic Describing a nonproliferating cell that has given up the option of ever again re-entering into an active growth-and-division cycle.

post-translational modification Covalent alteration of a protein occurring concomitantly with or after the initial polymerization of the polypeptide backbone of the protein, including cleavage of the initially synthesized polypeptide and covalent modification of its amino-acid side chains.

pre-clinical Referring to all of the steps in the research and development of an agent or therapeutic protocol leading up to but not including initiation of clinical testing.

pre-metastatic niche A site within a tissue that is altered in some fashion to facilitate the survival and/or proliferation of subsequently arriving disseminated cancer cells.

pre-mRNA The class of nuclear RNA molecules that are destined to become mRNA following their processing via splicing and export to the cytoplasm.

prenatal Occurring before birth. *See also* **natal**.

pre-neoplastic Referring to a tissue that has acquired certain features of a frank tumor but has itself not yet developed into a neoplasia. *See also* **neoplastic**.

presentation (1) The constellation of traits and symptoms exhibited by a patient upon examination in the clinic, often upon first encounter with a physician. (2) The set of symptoms and diagnostic parameters accompanying a disease when initially diagnosed.

primary Initial or initially formed.

primary cells (1) Literally, cells that have been recently explanted from living tissue into culture vessels and have not been propagated thereafter in culture. (2) More commonly, cells that have been explanted from living tissue into culture dishes and have been subjected to a relatively small number of successive *in vitro* passages thereafter.

primary cilium Single nonmotile cilium displayed by many types of mammalian cells which bears a specific set of receptors that confer responsiveness to various cytokines. *See also* **cilium**.

primary lymphoid organs The tissues in which immunoglobulin rearrangements initially occur, these being the thymus in the case of T lymphocytes and the bone marrow in the case of B lymphocytes.

primary resistance Term denoting the behavior of a tumor that is refractory to treatment from the onset of that treatment; *also termed* **intrinsic resistance**. *See also* **secondary resistance**.

primary tumor Tumor growing at the anatomical site where tumor formation began and proceeded to yield this mass. *See also* **metastasis**.

primase An enzyme that initiates DNA synthesis by laying down a short RNA segment on the template strand; the 3′-hydroxyl end of this RNA primer then serves as the site for attachment of the initial deoxyribonucleotide by a DNA polymerase. *See also* **primer**.

primer A DNA or RNA molecule whose 3′ end serves as the initiation point of DNA synthesis by a DNA polymerase.

priming The process that allows a specific set of converging signals to convert a naive T cell into a functionally activated derivative.

primitive (1) Referring to the relatively undifferentiated phenotype of a cell. (2) Referring to an embryonic cell.

private mutation A mutation that is present in a distinct subpopulation of cells or organisms and is not shared with the majority of cells or organisms in the population as a whole.

probe (1) An RNA or DNA, often radiolabeled, that anneals specifically with a complementary nucleic acid being analyzed, enabling the detection of the targeted nucleic acid sequence. (2) An immunological reagent used to detect an antigen or antibody.

procarcinogen A chemical compound that is relatively nonreactive chemically, but can be converted into a highly reactive carcinogen, usually through metabolic processes. *See also* **ultimate carcinogen**.

procaspase Protein that is converted to an active caspase enzyme by proteolytic cleavage. *See also* **caspase**.

processive Referring to a function of an enzyme in which it undertakes a succession of alterations of a substrate, doing so without dissociating from this substrate—e.g., a DNA polymerase extending a polynucleotide chain by hundreds of nucleotides without dissociating from the growing chain.

pro-drug An inactive precursor of a biologically active drug.

pro-enzyme Catalytically inactive precursor form of an enzyme that requires some type of alteration (often proteolytic cleavage) in order to become catalytically active.

professional antigen-presenting cell An immune cell (usually a dendritic cell or macrophage) that has, as one of its salient functions, the presentation within lymphoid tissues of antigenic peptides to T cells in lymphoid tissues. *See* **antigen-presenting cells**.

progenitor cell A cell derived from a stem cell whose descendants undergo a limited number of proliferative divisions before undergoing end-stage differentiation. *Also termed* **transit-amplifying cell**.

progeria Syndrome in which an individual undergoes premature or accelerated aging.

prognosis A prediction about the future clinical course of a disease, often influenced by detailed analyses of its existing attributes such as histopathology and biochemical markers.

programmed cell death One of several cell alternative death programs, such as apoptosis, that coordinate the process of cell death.

progression (1) The process whereby cells evolve progressively from a normal state to a state that enables them to form a high-grade malignancy. (2) The evolution of benign cancer cells to malignant derivatives. (3) The evolution of an initiated cell that is dependent on continued exposure to a tumor-promoting agent for its further proliferation into one that continues to proliferate in the absence of further exposure to the promoter. *See also* **initiation**, **promotion**.

progression-free survival Time elapsed following initiation of treatment during which a clinical condition does not worsen. *See also* **overall survival**, **disease-free survival**.

prokaryotic Referring to the relatively small, nonnucleated cells of bacteria and archaea. *See also* **eukaryotic**.

prolactin A polypeptide hormone made largely by the pituitary gland that stimulates mammary gland growth and milk production among other functions.

proliferation Process leading to increase in cell number and requiring passage through cells' growth-and-division cycle, often termed the **cell cycle**. *Compare* **growth**; *See also* **cell cycle**.

proliferation index Proportion of cells in a population that are proceeding through the active growth-and-division cycle.

prometaphase The phase of mitosis in the early part of metaphase when the nuclear membrane breaks down and the chromosomes form kinetochores. *See* **metaphase, kinetochore**.

promoter (1) An agent that furthers the progression of multi-step tumorigenesis by nongenetic mechanisms, notably those involving inflammation and/or mitogenesis, sometimes termed promoting agent. Tumor promoters are presumed to work by accelerating the rate of clonal

expansion of already-mutated cells. (2) The DNA sequence associated with a gene that controls its transcription. *See also* **promotion**.

promotion Process that stimulates or accelerates tumor progression, usually presumed to do so without directly damaging the genomes of cells. *See also* **promoter**, **initiation**.

promyelocyte An immature cell of the myeloid lineage that functions as precursor of various differentiated granulocyte cell types. *See* **granulocyte**.

proofreading Process by which a DNA polymerase scans the deoxyribonucleotide segment that it has just synthesized in order to ensure that the sequence of this segment was properly synthesized and thus is precisely complementary to that of the template strand. *See also* **mismatch repair**.

prophase First phase of mitosis in which chromosomes begin to condense and centrosomes begin to assemble.

prophylactic Preventative.

protease An enzyme that cleaves protein substrates.

proteasome A specialized intracellular multi-subunit machine that internalizes polyubiquitylated proteins and degrades them using specialized proteases, generating oligopeptides. *See also* **immunoproteasome**, **constitutive proteasome**.

proteoform A specific biochemical form of a protein that is defined by its primary amino acid residues together with a specific set of post-translational modifications. A single initially synthesized protein may be associated with multiple alternative proteoforms, each defined by its own combination of post-translational modifications.

proteoglycan Molecule with one or more glycosaminoglycan chains attached to a protein core. *See also* **glycosaminoglycan**.

proteolysis (adj., **-lytic**) Process, usually mediated by protease enzymes, of cleaving a polypeptide to lower–molecular-weight fragments including individual amino acids.

proteome The collection of all the protein species expressed by a cell, tissue, or organism.

proteomics (1) Technologies by which systematic analyses are made of large numbers of distinct protein species in a biological sample, such as a cell lysate or a biological fluid. (2) Enumeration of the set of proteins synthesized by a cell or tissue.

protomer A subunit—usually a single polypeptide chain— of a multi-subunit (oligomeric) protein.

proto-oncogene A normal cellular gene that, upon alteration by DNA-damaging agents or viral genomes, can acquire the ability to function as an oncogene. *See* **oncogene**.

protozoan Referring to single-cell eukaryotic animals that feed on other microorganisms or microbe-derived debris. *Compare* **metazoan**.

provirus The dsDNA copy of a retroviral genome that is the product of reverse transcription; it can exist transiently, as an episomal (nonchromosomal) plasmid, or stably, following its integration into the chromosomal DNA of an infected host cell.

pseudogene A gene present in the genome that shares extensive sequence similarity with known functional genes but encodes a defective function, such as a catalytically inactive enzyme; such pseudogenes invariably derive evolutionarily from functional genes that have sustained inactivating mutations in the distant past but have nonetheless persisted in an organism’s genome.

pseudokinase A protein domain that exhibits many of the structural features of a bona fide kinase and is a paralog of bona fide kinases but that lacks the catalytic activity of the latter because of amino acid replacements in the catalytic cleft.

pseudoligand A compound or substance that, although quite different from the actual normal ligand, can nevertheless bind to the ligand-binding site of a receptor, often doing so without activating signaling by the receptor.

pseudopregnant Referring to a female that has been placed in a physiological state that closely resembles that of pregnancy, achieved through exposure to certain hormones.

pulmonary Referring to the lungs.

purifying selection Process occurring during Darwinian evolution in which negative selection eliminates less-fit variants, leaving behind a population of cells or organisms that is most fit.

pulse-chase An experimental protocol in which a period of labeling, such as that involving incorporation of radioisotopes, is followed by a period in which further labeling is discontinued and may be actively blocked by agents that prevent further labeling.

pyknosis (also **pycnosis**) Chromatin condensation and shrinkage of nuclei creating small, densely staining structures observed as products of apoptosis and necrosis.

pyroptosis A cell death program that is often provoked by infection by intracellular pathogens and results in cell death and the release of pro-inflammatory cytokines. Pyroptosis can also be induced following exposure to certain chemotherapeutic agents.

qRT-PCR Procedure for quantifying the concentration of an RNA molecule by determining the number of PCR amplification cycles of its reverse transcript that are required to generate a certain threshold level of PCR-generated DNA products. *See also* **polymerase chain reaction**.

quartile Any one of four equal groups into which a large sample of individuals or test objects has been subdivided, being guided through the use of measurements of the properties of the individuals or test objects.

quasi-mesenchymal Referring to a phenotypic state between the fully epithelial and the fully mesenchymal states and involving the expression of a mixture of genes characteristic of both states.

R point *See* **restriction point**.

rad Unit of radiation corresponding to 0.01 joule of absorbed radiation per kilogram of exposed tissue or 0.01 gray.

radiation oncology The practice of treating tumors with various types of radiation. *See also* **medical oncology**, **surgical oncology**.

radioautography *See* **autoradiography**.

radionuclide An atomic species that undergoes radioactive decay, thereby emitting radioactivity. *Also termed* **radioisotope**.

radiosensitive Describing cells or tissues that are particularly sensitive to killing by radiation including that inflicted by radiotherapies.

radiotherapy Treatment of a disease, notably cancer, through irradiation, usually in the form of X-rays that, in the case of cancer treatment, are focused on a targeted tumor or tumor-bearing tissue.

rapalog A chemical analog of rapamycin. *See* **rapamycin**.

rapamycin A naturally occurring, low–molecular-weight inhibitor of mTOR. *See also* **mTOR**.

rate-limiting Referring to a step in a multi-step process that governs the overall rate at which the process as a whole reaches completion because this particular step is kinetically slower than all other steps.

reactive oxygen species A chemically reactive, oxidizing molecule that results from the incomplete reduction of oxygen, including notably superoxide, hydrogen peroxide, and hydroxyl radical; these reactive oxygen species damage a wide range of molecules in the cell, requiring compensatory anti-oxidant defenses to prevent or reverse this damage.

reactive stroma The stroma of a highly progressed tumor that has recruited a number of cell types that are typically associated with inflammation and wound healing, including prominently activated fibroblasts and myofibroblasts. *See also* **stroma**.

reader A protein that recognizes existing post-translational covalent modifications of histones within nucleosomes and responds by influencing the structure and/or function of the associated chromatin, thereby regulating processes such as transcription, DNA repair, and further histone modification. *See also* **writer**, **eraser**.

reading frame (1) The nucleotide sequence within a gene or mRNA that encodes the amino acid sequence of a protein. (2) The registration of triplet codons within this sequence that enables the proper translation of this protein sequence.

receptor Protein found on the plasma membrane or in the nucleus within a cell that is capable of specifically binding a signaling molecule (its cognate ligand). Most types of receptors emit signals, such as those inducing cell proliferation, in response to such binding. *See also* **ligand**.

recessive (1) Referring to one of several alternative traits that can be specified by a genetic locus; when the locus is heterozygous and carries information specifying two distinct traits, the dominant trait will be exhibited phenotypically by the organism and the recessive will not. (2) Referring to an allele of a gene that is unable to dictate phenotype when expressed in the presence of a second allele that acts dominantly. *See also* **dominant**.

reciprocal translocation Exchange via a process resembling recombination of chromosomal segments between two chromosomes from different (i.e., usually nonhomologous) chromosome pairs, resulting in the conservation of all participating chromosomal segments.

recombinant Referring to a protein that has been produced through the procedures of recombinant DNA.

recombinant DNA Technology that allows the isolation of genetic elements from organisms, often via the procedures of gene cloning, the experimental amplification of such segments, and their subsequent manipulation via various techniques of DNA alteration, with the intent of understanding the function of the isolated elements, altering them to generate useful gene products, or sequencing them in order to understand disease processes, genetic predilections, and relationships between organisms.

recombinase An enzyme that executes one or more steps of genetic recombination.

recurrent mutation Somatic mutations of a particular gene or nucleotide sequence that is observed in the genomes of a number of independently arising tumors, providing strong indication that mutations of this gene or sequence confer selective advantage to the cells that sustain them. *See also* **driver mutation**.

reductionism A scientific philosophy and research strategy that involves the study of individual, relatively simple components or subsystems of complex systems rather than the systems as a whole.

refractory Unresponsive or resistant to some type of signal or therapeutic agent.

regulatory B cells A subset of B cells that releases immunosuppressive signals. *Also termed* **B_{reg} 's**.

regulatory T cells A subset of CD4 lymphocytes that releases various immunosuppressive signals. *Also termed* **T_{reg} 's**.

rejection Process whereby the immune system of a host organism prevents the outgrowth of implanted donor cells or tissues, usually by the killing donor cells. *See also* **allograft rejection**.

relapse (1) (n.) Reoccurrence of a disease state, such as the reappearance of a tumor, after treatment with an initial, apparently successful therapy. (2) (v.) To sustain such a reoccurrence.

remission Retreat or disappearance of a disease state with the implied possibility of its eventual reappearance or worsening.

renal Referring to the kidney.

replication (1) Process involving the copying of a nucleic acid into more nucleic acid. Thus, DNA can be copied into progeny DNA and RNA can be copied into progeny RNA. (2) Proliferation of a virus in an infected cell.

replication cycle The program of molecular and biochemical changes that enables an infecting virus particle to multiply within a cell, generate progeny virus particles, and release these particles so that they may infect other cells.

replication fork The structure formed when a helicase enzyme locally unwinds a DNA double-helix, enabling the resulting single-strand DNAs to serve as templates for the synthesis of progeny double-helices. *See also* **stalled replication fork**, **replication stress**.

replication stress A physiological cell state that occurs when the normal coordination of DNA synthesis is perturbed, often in response to stalled replication forks, resulting in, among other consequences, the collapse of replication forks arising because of breakage of the persisting ssDNA and the resulting formation of dsDNA breaks. *See also* **replication fork**, **stalled replication fork**.

replicative immortality *See* **immortality**.

replicative senescence The cell state entered when chromosomal telomeres have undergone erosion or, more commonly, when cells have experienced cumulative physiological stress over multiple cell generations in culture due to suboptimal conditions of propagation. *See* **senescence**.

replicon A defined segment of (chromosomal) DNA that is replicated by the firing of a single origin of replication, in principle occurring once during each normal cell cycle. *See also* **origin of replication**.

repressed Referring to a gene that is not being expressed and therefore is not being transcribed.

repression Regulatory mechanism that causes shutdown of the expression (transcription) of a gene. *See also* **expression**.

repressor A protein involved in inhibiting gene transcription. *Compare* **activator**.

rescue To restore a phenotype, usually by specific genetic or epigenetic manipulation.

resection Removal by surgical excision.

resorption The osteoclast-mediated process of dissolving mineralized bone with attendant mobilization of calcium into the circulation.

restriction fragment length polymorphism Variation in DNA sequence that can be detected through its effect of allowing or preventing cleavage of a chromosomal DNA segment by a restriction enzyme.

restriction point Decision-making point in the late G_1 phase of the cell cycle at which a cell commits itself to either completing the remaining phases of the cell cycle, remaining in G_1, or exiting the active cell cycle and entering into G_0.

reticuloendotheliosis Tumor of monocyte/macrophage lineage common in chickens and turkeys.

retinoblastoma Pediatric tumor of the oligopotential stem cells of the retina.

retrotransposon A transposon that propagates throughout a cellular genome by specifying an RNA transcript that is reverse transcribed by the transposon-encoded reverse transcriptase followed by chromosomal integration of the resulting reverse transcript. *See* **reverse transcriptase**, **transposon**.

retrovirus A class of viruses that uses a reverse transcriptase enzyme to copy its genomic single-strand RNA into double-strand DNA that, after integration into a host cell chromosome, serves as template for transcription of viral mRNA and progeny viral genomes.

reverse transcriptase Enzyme capable of making a DNA complementary copy of an RNA molecule using the RNA molecule as template.

reverse transcription Enzymatic reaction whereby an enzyme, such as reverse transcriptase, copies an RNA template into a complementary DNA copy.

rheostat An electrical controller that can vary resistance continuously over a certain defined range, thereby moderating current flow over a continuous range.

ribosome The ribonucleoprotein complex that operates in the cytoplasm to translate the coding information of an mRNA to which it is bound into an amino acid sequence that yields as an end product a complete protein molecule.

risk factor A lifestyle practice or experience or inherited genetic determinant that is judged to affect the likelihood of the development of one or another pathological state. The importance of such a factor is gauged quantitatively and contrasted with the quantitative risk confronted by control populations, such as the general population, in developing such a condition.

Rituxan The chimeric anti-CD20 monoclonal antibody bearing a murine antigen-combining variable domain and a human constant domain. *Also called* **rituximab**.

RNAi The molecular pathway within cells that results in the post-transcriptional silencing of gene expression effected by microRNAs, siRNAs, and shRNAs. *See also* **microRNA, siRNA, shRNA**.

RNAseq A procedure used to survey the RNAs expressed within a cell population by reverse transcribing these RNAs followed by sequencing the

resulting cDNA molecules. *See also* **scRNAseq**.

rosette A set of repeating objects, such as cells, arrayed in a circle, reminiscent of the shape of a rose.

RT-PCR Procedure of reverse transcription of mRNAs followed by PCR to amplify resulting reverse transcripts; this procedure employs the powers of DNA sequencing to gauge the representation of various mRNAs within the transcriptome of a cell or tissue. *See also* **polymerase chain reaction, qRT-PCR**.

sagittal Referring to a geometric plane through an organism that divides the organism into a right and a left half.

salvage chemotherapy A round of chemotherapeutic treatment given to a patient who initially responded well to an initial round of chemotherapy but then relapsed.

Sanger Cancer Genome Project The program undertaken by the Wellcome Trust Sanger Institute in the United Kingdom to identify sequence variants that are critical to the development of human cancers, including the assembly of the Catalogue of Somatic Mutations in Cancer.

sarcoma Tumor derived from mesenchymal cells, usually those constituting various connective tissue cell types, including fibroblasts, osteoblasts, endothelial cell precursors, and chondrocytes.

satellite Highly repetitive sequences present in genomic DNA. These sequences often have a different composition of bases compared to that of the bulk of the genomic DNA and thus form separate “satellite” bands that can be resolved upon isopycnic density centrifugation. *See also* **isopycnic**, **microsatellite**.

scaffold The structural backbone of a complex organic molecule that can be covalently modified (derivatized), often through the attachment of side groups, in order to create variants with differing pharmacological properties.

Schwann cells A cell that wraps itself around axons and secretes myelin, forming the myelin sheath that electrically insulates axons and facilitates transmission of electrical signals by the axons. *See also* **myelin**.

schwannoma Tumor of the Schwann cells.

scRNAseq *See* **single-cell RNA sequencing**, **RNAseq**.

second-line therapy The mode of therapy that is employed after a patient has been previously treated with a first-line therapy that has failed. *See also* **first-line therapy**.

second messenger A low–molecular-weight molecule that functions as an intracellular hormone, conveying signals from one part of a cell to another.

secondary resistance Term denoting the behavior of a tumor that was initially responsive to a treatment but subsequently becomes refractory to that treatment; *also termed* **acquired resistance**. *See also* **primary resistance**.

secretome The collection of proteins that are released by a cell into the extracellular space under specific physiological conditions or states of differentiation, often focused on signaling proteins.

section A slice, e.g., through a tissue.

seed-and-soil Hypothesis enunciated by Stephen Paget that describes the tendency of disseminated cancer cells from a specific type of primary tumor to preferentially colonize one or another distant tissue based on the biological compatibility between the disseminated cancer cells and the tissue in which they have landed.

segregation (1) Separation of chromosomes at the end of mitosis or meiosis. (2) Separation of alleles during meiosis.

selectin A cell surface receptor that enables a cell to bind to carbohydrate moieties expressed by other cells, such as those forming the luminal walls of blood vessels.

selective estrogen receptor modulator A pharmacological agent that binds as a pseudo-ligand to the estrogen receptor and perturbs its behavior in one way or another. *See* **pseudoligand**.

selectivity Relative ability of a therapy to affect targeted cells or tissue compared with its (side) effects on non-targeted normal cells or tissue. *See also* **therapeutic index**.

self A constituent of the body that is native to the body's normal tissues and associated cells. *See also* **non-self**.

self-antigens Antigens that are expressed in the body's normal tissues.

self-reactive Referring to the ability of certain components of the immune system of an organism to recognize and react with the normal tissue and normal cellular antigens of that organism, potentially resulting in the development of an autoimmune condition.

self-renewal Trait that enables a cell, usually a stem cell, to generate, upon cell division, at least one daughter cell that retains all of its traits. *See also* **stem cell**.

self-seeding *See* **tumor self-seeding**.

seminoma A tumor of the epithelial cells forming in the seminiferous tubules of the testes.

senescence A nongrowing state of cells in which they exhibit distinctive cell phenotypes and remain viable for extended periods of time but are generally unable to proliferate again; senescence often arises after extended passaging of cells *in vitro*, notably under suboptimal conditions of culture. *See* **replicative senescence**.

senescence-associated heterochromatin foci Domains of heterochromatin that form in senescent cells and contribute to the silencing of proliferation-promoting genes in such cells.

senescence-associated secretory phenotype A condition observed in some cells undergoing senescence that is associated with the secretion of certain pro-inflammatory cytokines, immune modulators, proteases, and growth factors.

sequence motif (1) Short oligonucleotide sequence in DNA that is characteristically associated with one or another biological function including recognition and binding by sequence-specific transcription factors. (2) Amino acid sequence that is characteristically associated with a structural or functional aspect of a protein.

sequencing depth The degree of redundant sequencing of a DNA segment or a DNA genome.

serial passaging Practice of transferring a cell population or viral population from one culture vessel or host cell to another, taking the products of this initial passage, and transferring a portion of them to yet another host cell or culture vessel to allow a new cycle of proliferation, doing so serially and repeatedly. *See* **passaging**.

serpentine Referring to the class of membrane proteins, such as G protein-coupled receptors, that wend their way back and forth (in a snakelike pattern) through a membrane multiple times.

serum (pl., **sera**) The fluid left behind when blood clots.

set point A state to which a complex regulatory system naturally reverts in the absence of strong external perturbants; set points are often maintained through homeostatic regulatory mechanisms. *See* **homeostasis.**

shelterin A complex of at least six proteins that binds to the ssDNA and dsDNA regions of telomeres and functions together with the telomeric DNA to protect the ends of chromosomal DNA from end-to-end fusions.

shRNA A sequence of ~60 nucleotides that is cloned into an expression vector that produces a hairpin transcript. This transcript is cleaved by cellular enzymes into a 21- to 25-nt-long dsRNA that is partially

complementary to the mRNA target that it is designed to inhibit. *See* **hairpin**.

shunt A passageway or connection that allows fluid to pass directly from one place to another, such as the direct connection between an artery and a vein that occurs without blood passing through intermediate microvessels, i.e., capillaries.

side effect A biological or biochemical effect of an applied treatment that elicits a response other than the intended one.

single-cell RNA sequencing A procedure in which the RNA transcripts of individual cells are reverse transcribed; the resulting DNA molecules are then amplified and subjected to next-generation DNA sequencing, revealing the transcriptomes of each of such cells. *See also* **next-generation sequencing**.

single-chain variable region fragment An antigen-binding polypeptide that is formed by connecting the variable domains of the heavy and light chains of an immunoglobulin via an intermediate linker; this fusion protein can function like the parental, naturally formed antibody to recognize and bind a specific antigen.

single-nucleotide polymorphism A polymorphism within the gene pool of a species that differs by a single nucleotide from homologous sequences that are present in the genomes of other individuals of the species. Such polymorphisms are generally assumed to be functionally and thus phenotypically silent. *See* **polymorphism**.

sinusoid A capillary-like channel located between liver hepatocytes that is lined with endothelial cells but lacks mural cells as well as a capillary basement membrane. *See also* **mural**.

siRNA A 21- to 25-nt-long dsRNA molecule that is synthetically produced and introduced into cells in order to interfere with the expression of a targeted mRNA with which it typically shares partial complementarity. *See also* **RNAi**.

sister chromatids The two chromatids that are formed from the two double helices synthesized following the most recent round of DNA replication and that remain joined via a pair of kinetochores associated with their respective centromeres until they are eventually separated from one another during mitosis.

small-cell lung carcinoma Lung cancer of specialized pulmonary cells having neurosecretory properties.

smoldering Referring to slow combustion releasing smoke but no flames.

soft-tissue sarcoma A sarcoma arising in a tissue other than bone.

soma All the tissues in the body outside of the germ cells (sperm and egg) and the immediate precursors of the germ cells.

somatic hypermutation Enzyme-mediated process, notably that effected by activation-induced deaminase, that creates point mutations in the already-rearranged immunoglobulin genes, largely focused on their V region-encoding segments and generating greatly increased antigen-binding diversity. *See also* **activation-induced deaminase**.

somatic mutation Mutation that strikes the genome of a cell outside of the germ line; such a mutation cannot, by definition, be transmitted to the next organismic generation. *See also* **germ line**.

Southern blot Procedure in which DNA molecules, usually produced by restriction enzyme cleavage, are resolved by gel electrophoresis and transferred to a filter to which they adsorb; the filter is subsequently incubated with a sequence-specific radiolabeled DNA probe to reveal, upon subsequent autoradiography, the sizes of the DNA fragments recognized by the probe. *See also* **Northern blot**, **Western blot, autoradiography**.

speciation The formation during the course of evolution of a new species from a preexisting one or the development of two new species from a preexisting one, the latter often enabled by the geographical isolation of two subpopulations of the original species from one another.

spectral karyotyping A procedure that allows the “painting” of individual chromosomes in a metaphase spread using chromosome-specific DNA probes coupled to five or more specific fluorochromes, achieved via fluorescent *in situ* hybridization and informatics to process and generate the colors exhibited in the finished karyotypic image.

spheroid Small, sphere-shaped cluster of cells typically observed when cells are propagated *in vitro* in three-dimensional matrices.

spindle The array of microtubule spindle fibers that originate at and radiate from the two oppositely located centrosomes and extend to the kinetochores of chromosomes, being involved in segregating chomosomes during mitosis and meiosis. *See also* **centrosome, kinetochore**, **spindle fiber**.

spindle assembly checkpoint The complex mechanism that monitors proper attachment of spindle fibers to kinetochores and blocks entrance into the anaphase of mitosis and meiosis if these attachments are not properly formed.

spindle fiber A microtubule fiber that extends from a centrosome to the kinetochore of a chromosome and is formed during meiosis and mitosis. *See also* **kinetochore**, **centrosome**, **spindle**.

splenocyte A leukocyte isolated from the spleen, which may belong to B or T cell populations as well as myeloid-derived populations, such as macrophages and dendritic cells.

splice site A sequence on a nuclear RNA molecule that determines the precise location of one of the two sequences that are fused to one another during the process of splicing.

splicing (1) Process that causes the deletion of a defined internal segment of a primary RNA transcript and the subsequent fusion of the two RNA segments flanking the deleted RNA segment. (2) Process occurring in the nucleus whereby a pre-mRNA precursor is converted into an mRNA through the deletion of introns and the fusion of remaining exons.

splicing factor Protein involved in regulating the process of splicing including the recognition of appropriate splice sites in the RNA molecule serving as the substrate of the splicing. *See also* **splice site**, **splicing**.

sporadic Describing a disease or condition that appears to occur randomly in a large population without any apparent inborn predisposition.

squamous Referring to epithelial cells that line a duct, hollow organ, or the skin and lack secretory function.

squamous cell carcinoma Tumor arising from squamous cells. *See also* **adenocarcinoma**.

staging A determination of the extent to which a tumor has progressed to a specific stage of multi-step tumor progression, involving consideration of an array of gross/macroscopic, histopathological, and karyotypic parameters.

stalled replication fork A DNA replication fork that, because of various impediments, cannot proceed further to replicate a DNA double helix; such stalled forks represent a potential physiological stress on a cell because of the persistence of single-strand DNA at the fork and the attendant danger of its breakage, resulting in turn in double-strand DNA breaks in the DNA being replicated. *See* **replication fork**.

standard of care The therapeutic agent or protocol that is widely accepted in the treatment of disease and often serves as the reference against which candidate novel treatments are measured.

standardized incidence ratio Ratio of the observed incidence of an event in a subpopulation of interest, such as a disease diagnosis, with the incidence of such an event that would be observed in a comparable control population, such as the general population.

start site The site in a gene at which an RNA polymerase initiates elongation of a nascent RNA transcript, also termed transcription start site.

steady state The condition reached when a series of dynamic, often countervailing processes have placed a complex system in a balanced, relatively constant, unchanging state.

stem cell Cell type within a tissue that is capable of self-renewal and is also capable of generating daughter cells that develop new phenotypes, notably those that are more differentiated than those displayed by the stem cell. *See also* **asymmetric division**.

stereochemistry Description of the three-dimensional structure of a molecule (such as a protein or drug) and the influence that this structure exerts on the chemical behavior or biochemical function of the molecule.

stochastic Referring to an event that occurs randomly with a certain probability rather than in a precisely predetermined fashion.

stock A solution of viruses that is used experimentally to infect cells or organisms.

stoichiometric Referring to a relationship or reaction between two or more molecular species in which the relative molarities of the participating species are precisely specified.

stratify (n., **stratification**) To classify superficially similar entities (e.g., a group of tumors) into several distinct categories or subclasses based on the shared properties of the entities within a given subclass.

stress-induced ligand A cell surface protein that signals that the cell displaying this protein is suffering from some type of cell physiological stress.

stressor An agent that imposes some type of physiological stress.

stroma (pl., **stromata**; adj., **stromal**) (1) The mesenchymal components of normal epithelial and hematopoietic tissues, which may include fibroblasts, adipocytes, endothelial cells, and various immunocytes as well as associated extracellular matrix. (2) A spectrum of similar cell types that constitute the stromal cells within a tumor and are recruited into the tumor

from host tissues and lack the somatic mutations born by the tumor cells. *See also* **reactive stroma**.

stromalization Referring to the process by which stroma is generated in a normal or neoplastic tissue including the formation of stroma-associated extracellular matrix.

structure-based drug design Use of the three-dimensional structure of a drug target, such as a protein, often determined by X-ray crystallography or nuclear magnetic resonance spectroscopy, in order to predict the chemical structures of compounds that will bind the target specifically and with high affinity, usually inhibiting its function.

subclinical Referring to a state or process that does not elicit specific symptoms and/or eludes detection by available diagnostic tools.

subcutaneous Beneath the skin.

submicroscopic Too small to be seen through the light microscope.

substrate (1) Molecule that is acted upon by an enzyme, usually resulting in the covalent modification of the substrate. (2) A physical structure upon which entities such as cells reside.

subtelomeric Referring to a segment of DNA that contains imperfect copies of the telomeric hexanucleotide sequence, does not function to protect the ends of chromosomal DNA, and lies between the functional telomeric DNA and the bulk of chromosomal DNA.

SUMO One of a group of four ubiquitin-like polypeptides that, like ubiquitin, are attached covalently to substrate proteins, thereafter affecting intracellular localization and functions of the modified proteins but not their degradation.

sumoylation The process of modifying a protein by covalently attaching one or more SUMO molecules to it. *See also* **SUMO**.

super-enhancer A large cohort of transcription factors, each bound to its cognate enhancer sequence, that assemble in a physical complex and drive the high-level expression of a nearby gene. *See also* **enhancer**.

supernatant Fluid that is formed after solids are removed via centrifugation or solutes by precipitation or crystallization. *Also termed* **supernate**.

supernumerary Referring to a greater-than-normal number of some object.

superoxide Reactive ion arising from addition of an electron (reduction) to diatomic oxygen.

superoxide dismutase An enzyme that catalyzes the conversion of 2 superoxide molecules into one diatomic oxygen molecule (O_2) and one hydrogen peroxide (H_2O_2) molecule. *See also* **superoxide**.

supranormal Higher than normal physiological levels.

surgical oncology The practice of treating tumors surgically, usually by excision. *See also* **medical oncology**, **radiation oncology**.

surrogate marker A measurable parameter, often a diagnostic parameter, that serves to indicate the behavior of another process or agent whose behavior it parallels and reflects.

survivin Member of the IAP family of proteins that functions by inhibiting certain pro-apoptotic caspases.

symmetric division The process whereby a mother cell yields, following cell division, two identical daughter cells. *See also* **asymmetric division**.

synapse Physical connection formed between two interacting immune cells or between a cytotoxic lymphocyte and a targeted cell that facilitates exchange of signals between them and, in the case of cytotoxic cells, the transfer of cytotoxic granules from the cytotoxic cell to the targeted cell.

synchronous (1) Occurring at the same time; i.e., in a temporally coordinated fashion. (2) Referring to a population of cells that enter a specific phase of the cell cycle at the same time. *See also* **asynchronous**.

syncytium Cell formed when the plasma membranes of two or more cells fuse, initially resulting in a multi-nucleated cell.

syndrome Collection of symptoms and pathologies that are associated with and together define a specific disease condition.

syngeneic (1) Referring to two organisms that share the identical genetic background, such as two members of an inbred strain of mice. (2) Describing the relationship between two sets of cells or tissues, or between a set of cells and an organism, deriving from identical genetic backgrounds.

synonymous Referring to a mutation in a reading frame that does not change the identity of an encoded amino acid. *See also* **nonsynonymous**.

synthetic lethal (1) Describing phenotypes that result from the combined effects of two alleles, each of which is nonlethal on its own, but which, when present in combination, result in lethality. (2) Referring to a state in which an existing genetic or epigenetic condition renders a cell vulnerable to killing by one or another applied agent, such as a therapeutic agent.

synthetic lethal screen A screen of a large number of genes, often those present in an entire genome, in which the cells introduced into the screen bear one or another mutation; the subsequent screen is designed to detect, in an unbiased fashion, other genes that, when disrupted, lead to lethality in these cells but not in wild-type cells lacking the mutation.

T antigen Tumor-associated antigen, such as that encoded by the genome of a transforming tumor virus such as SV40 and the genomes of the cells that it has transformed. *See* **tumor-associated antigen**.

T cell Class of lymphocytes that develops largely in the thymus and includes T_H cells, T_C cells, and T_{reg}'s.

T-cell exhaustion State of a T cell that has been induced by prolonged, possibly excessive antigen exposure as well as by exposure to certain cytokines, and is associated with loss of its various effector functions.

T-cell receptor The immunoglobulin-like molecule that is displayed on the surface of T cells and used by them to recognize antigens displayed by HLA/MHC class I or class II proteins on the surfaces of other cells, including professional antigen-presenting cells and potential target cells.

T-loop *See* **activation loop**.

t-loop Lasso-like structure at the end of a telomere that serves to protect the termini of a chromosomal DNA molecule from end-to-end fusions and degradation by exonucleases.

T lymphocyte *See* **T cell**.

tamoxifen A synthetic pharmacological analog of estrogen which can bind the estrogen receptor and inhibit a subset of the normal signaling functions of this estrogen-activated receptor, thereby antagonizing the actions of estrogen.

telomerase An enzyme specialized to extend telomeric DNA; those telomerases characterized to date carry an RNA subunit and a reverse transcriptase-like catalytic subunit. *See also* **telomere**.

telomere Nucleoprotein structure at the end of a eukaryotic chromosome that protects this end from degradation and from fusion with the ends of other chromosomes.

telophase Fourth subphase of mitosis, during which chromosomes de-condense and the nuclear membranes reassemble in anticipation of separation of the two daughter cells.

temozolomide A chemotherapeutic drug used primarily in the treatment of certain brain tumors. It is a type of alkylating agent that causes direct DNA damage.

temperate A type of behavior (e.g., of an infectious agent, such as a virus) that creates minimal damage or pathology in an infected host cell or organism. *See also* **virulent**.

temperature-sensitive Describing a phenotype that is apparent when cells or viruses grow at one temperature but not at another.

tetramer Complex composed of four subunits.

teratogen An agent that causes malformations by perturbing embryonic morphogenesis.

teratoma Benign tumor formed by embryonic stem cells in which a wide variety of differentiated cell types are formed.

term The period of time required to complete a normal pregnancy.

ternary (1) Referring to a complex of three components. (2) Referring to the third step in a multi-step process.

TET A class of enzymes that operate to oxidize the methyl moiety of 5-methyl cytosines in the DNA, ultimately yielding demethylation of this base.

tetraploid Describing a karyotype having precisely four haploid complements (or two diploid complements) of chromosomes.

tetraspanin A relatively small protein with four transmembrane domains that operates in various membranes to modulate signaling by a wide variety of other transmembrane proteins such as receptors.

The Cancer Genome Atlas A project to identify the complete set of DNA changes in many different types of cancer, led by the U.S. National Cancer Institute and the U.S. National Human Genome Research Institute.

therapeutic index (pl., **indices**) The ratio of the concentration of a drug that elicits an unacceptable level of toxicity compared with the concentration of the drug that elicits a desirable therapeutic response.

therapeutic range *See* **therapeutic window**.

therapeutic window Range of concentrations of a drug that are higher than that needed to elicit a therapeutic effect and lower than the maximum tolerated dose. *Also termed* **therapeutic range**.

thrombin A plasma protease that is activated following wounding and triggers blood coagulation by activating platelets and cleaving fibrinogen to fibrin.

thrombocyte A platelet.

thrombocytopenia A deficiency of platelets in the circulation.

thromboembolus *See* **embolus**.

thrombopoiesis Process leading to the formation of blood platelets from megakaryocytes.

thrombopoietin A growth factor that stimulates the production of megakaryocytes and thus of derived blood platelets.

thrombus (pl., **thrombi**) A blood clot.

thymocyte A leukocyte residing in the thymus.

thymus The immune organ lying in the upper chest and front of throat in which the maturation of thymocytes occurs, including the elimination of autoreactive thymocytes

time-lapse microscopy Procedure in which the same microscope field is photographed repeatedly, usually at regular intervals.

time to progression The period between inception of a treatment and the subsequent progression of a tumor under treatment to a stage of worse clinical presentation or higher stage of malignancy.

tissue culture Procedure of propagating cells outside of living tissues in various types of vessels including flasks and Petri dishes.

Tissue Factor A cell-surface glycoprotein expressed by many cell types in the body that interacts with clotting factors in the plasma, thereby triggering the coagulation cascade.

tissue-specific gene Gene that is expressed only in cells of certain individual tissue types.

titer Concentration of a substance in solution, usually referring to the concentration of viruses or antibodies as gauged by certain biological measurements involving dilution.

tolerance *See* **immune tolerance**.

tomography A computerized image-processing technique that integrates images of successive sections obtained by X-rays, ultrasound, or by other imaging procedures in order to generate a cross-sectional image or a three-dimensional image of an object, such as the human body.

topoinhibition *See* **contact inhibition**.

topoisomerase (1) An enzyme that relieves torsional tension in a DNA double helix by cleaving one or both strands, permitting winding or unwinding of the helix to relieve tension; thereafter this enzyme, ligates the DNA strand(s), thereby restoring the covalent integrity of the helix. (2) An enzyme that disentangles two intertwined, concatenated dsDNA molecules.

totipotent Referring to the ability of a stem cell to generate all the differentiated cell lineages existing in the embryo as well as the extraembryonic membranes. *See also* **multipotent**, **pluripotent**.

toxicity The undesired side effect(s) of a drug on normal tissues and normal metabolism.

trafficking The process of translocating biological entities, usually vesicles, from one intracellular locale to another.

trans (1) Term to indicate the fact that a gene is acted upon by the product of a second, unlinked gene. (2) Term used in structural organic chemistry to

indicate that two moieties are oriented in opposite directions or located on opposite sides of an imagined plane. *See also* **cis**.

trans-acting Referring to a protein, often a transcription factor, that is encoded by one gene and acts upon or regulates a second gene.

transactivation Process by which one molecule is activated by another that arrives from elsewhere in the cell; e.g., expression of a gene that is induced by a diffusible transcription factor made by another gene. *See also* **cis, trans**.

transactivation domain Domain of a transcription factor that serves to activate the transcription of genes, usually by attracting other transcription-regulating proteins.

transcription Copying of DNA sequences into RNA molecules mediated by RNA polymerases.

transcription-coupled repair A form of nucleotide excision repair (NER) in which transcribed regions of the genome are preferentially repaired. RNA polymerase stalled at DNA lesions mediates the recruitment of NER enzymes to the damage site, initiating transcription-coupled repair.

transcription factor Protein that is involved in regulating the transcription of a gene, often by associating with specific sequences in the promoter region of the gene. *See also* **general transcription factor**.

transcriptional pausing The process causing an RNA polymerase II molecule that has initiated transcription of a gene to halt at a downstream site relatively close to the transcriptional start site; formation of a full-length transcript depends on release of the polymerase from the site of pausing.

transcriptome (1) The assembly of all of the transcripts that are produced by one cell or cell type. (2) More commonly, the assembly of all of the mRNAs produced by one cell or cell type.

transdifferentiation Transition by a cell from one differentiation lineage into the phenotypic state characteristic of cells from another, distinct differentiation lineage.

transduction (1) Process whereby a signaling element, such as a protein, receives a signal and, in response, processes the signal and emits another signal. (2) Process by which a gene is introduced into a cell, usually by a vector such as a viral vector.

transfectant A recipient cell that has taken up and incorporated into its genome transfected donor DNA.

transfection A procedure for introducing DNA or RNA molecules into cells which may thereafter be expressed transiently in such cells or, in the case of DNA, stably in such cells.

transferase An enzyme that attaches a complex molecule, such as glutathione, to its substrate.

transformant A neoplastic cell that is formed by the experimental transformation of a non-neoplastic cell. *See* **transformation**.

transformation (1) Process of converting a normal mammalian cell into a cell having some or many of the attributes of a cancer cell. (2) Alteration of a cell through the introduction of a genetic element, usually referring to a process occurring in prokaryotic cells.

transgene (1) A cloned gene that has been inserted experimentally into the germ line of an animal, often that of a laboratory mouse. (2) Less commonly, any experimentally altered gene in the germ line.

transgenic (1) Referring to an animal or breed of animal whose germ line has been experimentally altered, usually through the insertion of a cloned gene. (2) Less commonly, referring to an animal or breed of animal whose germ line has been altered through any of a variety of genetic manipulations, including the addition of a cloned gene or the alteration of a resident gene through homologous recombination or other procedure.

transit-amplifying cell A relatively undifferentiated cell that is initially generated by division of a stem cell and is capable of exponential proliferation for a limited number of successive cell generations before spawning highly differentiated progeny, which in many tissues become post-mitotic. *See also* **progenitor**.

transition Point mutation in which one purine base replaces another, or in which one pyrimidine base replaces another. *See also* **transversion**.

translation Synthesis of proteins by ribosomes in which the amino acid sequences of the synthesized proteins are dictated by the nucleotide sequences of the ribosome-associated mRNA molecules. *See also* **ribosome**.

translocation (1) Rearrangement of chromosomes that results in the fusion of two chromosomal segments that are not normally attached to one another, often resulting in a microscopically visible alteration of karyotype. (2) Movement of a physical entity from one part of the cell to another. (3) Movement of a ribosome down an mRNA being translated.

transmembrane Referring to the domain of a protein, usually composed of a stretch of 12 to 35 hydrophobic amino acids, that is threaded through a lipid bilayer membrane and therefore resides largely or entirely within the hydrophobic environment of the lipid bilayer.

transphosphorylation Phosphorylation of one protein molecule by another, such as the phosphorylation of one receptor subunit by the kinase carried by another. *See also* **autophosphorylation**.

transposable element DNA segment residing in a cellular genome that is capable of either jumping from one integration site to another or dispatching new copies of itself to novel sites of integration, doing so via one of several alternative molecular mechanisms.

transposase Enzyme that binds transposon DNA and causes its copying and insertion into novel integration sites in a cellular genome. *See also* **transposon**, **transposable element**.

transposon Genetic element or DNA segment that is able to move from one chromosomal integration site to another within a cell. *See also* **retrotransposon**.

transversion Point mutation in which a purine base replaces a pyrimidine or vice versa. *See also* **transition**.

trastuzumab *See* **Herceptin**.

tricarboxylic acid cycle The succession of biochemical reactions occurring within the mitochondria that results in the oxidation of a glucose molecule, yielding the equivalent of ~38 ATP molecules. *Also termed* **Krebs cycle**, **citric acid cycle**.

trimeric Complex composed of three subunits.

triploid Describing a karyotype or a genetic state having precisely three haploid complements of a chromosome, chromosomal array, or copies of a gene.

tritium Radioactive isotope of hydrogen.

trophic Aiding in or supporting cell growth, proliferation, or survival.

-tropic Referring to a tendency of a cell or an organism to move toward or turn toward some object or source or to direct its actions toward that source.

tropism (1) Tendency of a cell to face or move toward a specific location or signaling source. (2) Tendency of a cell to migrate in a specific direction or, in the case of metastatic cancer, to appear to home to a specific tissue site in the body.

truncal Referring to a genetic alteration that is present in the genomes of all of the otherwise-heterogeneous neoplastic cells within a tumor and is indicative of their shared descent from a common ancestral cell; such mutations are associated with the trunk of a branched tree drawn to depict graphically the evolutionary history of these cells from their common ancestor.

t-SNE A graphical convention in which the data present in high-dimensional datasets can be reduced via a statistical method to a two- or three-dimensional depiction; t-SNE plots are often used to depict results of single-cell RNA sequencing, such that cells with similar transcriptomes are clustered together with one another. *See also* **scRNAseq**.

tumor-associated antigen An antigen that is associated with the cells of a tumor and may also be displayed by normal cells or tissues throughout the body; *also termed* **tumor-associated transplantation antigen**. *Compare* **tumor-specific antigen**.

tumor-associated macrophage A macrophage that has been recruited into a tumor.

tumor-associated transplantation antigen An antigen encoded by a normal cellular allele that is expressed by a certain class of tumors and may have, for various reasons, not elicited immune tolerance. *See also* **tumor-specific antigen**.

tumor-initiating cell *See* **cancer stem cell**.

tumor microenvironment The areas within a tumor that are populated by recruited non-neoplastic cells, including various types of immunocytes and inflammatory cells, often synonymous with stroma. *See also* **stroma**.

tumor mutational burden The total number of mutations found in the genomic DNA of tumor sample, often presented as number per haploid genome or per megabase of genomic DNA.

tumor progression (1) Process of multi-step evolution of a normal cell into a fully neoplastic, malignant tumor cell. (2) Evolution of a benign into a malignant cancer cell or growth. (3) Evolution of a premalignant cell from a promoter-dependent to a promoter-independent state.

tumor promoter *See* **promoter**.

tumor rejection Process by which an organism prevents the formation of a tumor (including tumor formation by engrafted cells), usually achieved

through the action of its immune system.

tumor self-seeding Process whereby circulating tumor cells originating in a primary tumor or in its derived metastases return to the primary tumor and seed populations of cells within that tumor.

tumor-specific *See* **tumor-specific antigen**.

tumor-specific antigen An antigen that is associated with the cells of a tumor that is unique to this tumor and is not shared by other cells or tissues throughout the body; *also termed* **tumor-specific transplantation antigen**. *See also* **tumor-associated antigen**.

tumor-specific transplantation antigen An antigen that can, through transplantation analyses, be associated with one particular tumor cell population but not with other similar tumor cell populations. *See also* **tumor-specific antigen**.

tumor suppressor gene (1) A gene whose partial or complete inactivation, occurring in either the germ line or the genome of a somatic cell, leads to an increased likelihood of cancer development. (2) Such a gene that is responsible for constraining cell proliferation. *See also* **gatekeeper**.

tumoricidal Able to kill cancer cells and/or destroy a tumor.

tumorigenesis The process of forming a tumor, often involving a succession of steps.

tumorigenic (1) Referring to the ability of cells to form tumors when introduced into appropriate animal hosts. (2) Less commonly, pertaining to an agent such as a tumor virus that imparts this ability to cells.

tumorigenicity The ability of cells to serve as founders of new tumors, often gauged experimentally by transplanting cells into appropriate hosts.

tumorsphere A colony of cells that is formed in semi-solid culture medium by cells that are deprived of contact with solid substrate; the ability to form such colonies is sometimes used to predict tumor-forming ability *in vivo.*

turnover number The rate with which an enzyme processes its substrate, usually presented as the number of enzymatic reactions catalyzed per second by a single enzyme molecule.

type IV secretion system A collection of structures formed by bacteria and archaea that create a channel through which bacterial and archaean proteins are delivered through the outer membranes of other cells.

ubiquitin A polypeptide composed of 76 amino acid residues that undergoes covalent attachment to a substrate protein, often signaling that the resulting ubiquitylated protein is destined for degradation and usually present as a linear or branched polyubiquitylated modification of the substrate protein.

ubiquitylation Process by which one or more ubiquitin molecules are attached covalently to a protein substrate molecule, which often results in the degradation of the tagged protein in a proteasome, *alternatively termed* **ubiquitination**.

ultimate carcinogen A chemical compound that is able to directly contribute to the induction of cancer without further chemical modification, usually by direct chemical interaction with DNA, thereby altering the chemical structure of the latter. *See also* **procarcinogen**.

undruggable Referring to a molecular species within a cell, usually a protein, whose function cannot be readily inhibited by existing drug molecules or, ostensibly by alternative drug molecules that might be developed in the future; such a property is often judged by the absence of potential drug-binding pockets in the known three-dimensional structure of the species.

unequal crossing over A mechanism of genetic recombination in which a DNA sequence recombines with a nonidentical but similar sequence on either the sister chromatid or a homologous chromosome; because the recombination occurs between two nonidentical DNA sequences, one of the resulting recombinant chromosomes will gain sequence (and physical length), whereas the other will lose sequence (and physical length).

unfolded protein response A cell-biological program, which is the main source of ER stress, that is activated by the accumulation of unfolded or misfolded proteins in the lumen of the endoplasmic reticulum; this program halts further translation, induces synthesis of molecular chaperones, and, if unsuccessful in reducing the level of unfolded and misfolded proteins, induces apoptosis. *See* **ER stress**.

urothelium The specialized epithelial cell lining of the urinary bladder.

uveal melanoma A tumor arising from the melanocytes of the uvea, more specifically located in the iris, the ciliary body, or the choroids of the eye.

vacuoles Small, fluid-filled, bubble-like structures, often seen in the cytoplasm of cells that are under physiological stress and in cells infected by certain viruses.

variable region Portion of an antibody molecule or T-cell receptor that contains the antigen-binding domain and, within an individual organism, is present in millions of alternative versions (and thus alternative amino acid sequences) in the various antibody molecules that together comprise a given class of antibody molecules such as gamma immunoglobulin. *Compare* **constant region**.

vascular ZIP code The display by the luminal surfaces of endothelial cells of specific proteins that reflect or are specific to the tissue in which the endothelial cells and the vessels they form reside; one theory of metastasis proposes that circulating cancer cells adhere to the vessel walls by recognizing the specific homing address created by these displayed proteins.

vascularized Referring to the presence of blood vessels throughout a tissue such as a tumor.

vasculature Network of blood vessels.

vasculogenesis Process by which vessels are assembled *de novo* through the differentiation program of primitive mesenchymal proteins termed angioblasts. *Compare* **angiogenesis**.

vasculogenic mimicry The process that enables the neoplastic cells within a tumor to assemble into blood-carrying microvessels without these cells becoming *bona fide* endothelial cells.

vasoactive Referring to a regulator of vascular function, such as a regulator of vascular permeability or constriction.

vector (1) Agent, often a virus, that is able to carry (transduce) a gene from one cell to another. (2) An infected organism that serves to transmit and distribute an infectious agent to other organisms.

vehicle The solvent that is used to deliver a drug.

venereal Involving or resulting from sexual intercourse.

Venn diagram Diagram of two or more circles, each of which encompasses a group of items such as genes; the overlap between two circles indicate the items that are shared in common between the groups represented by each of these circles.

ventral (1) Referring to the underside of a cell that is apposed to a solid substrate such as the surface of a culture dish. (2) Referring to the side of an organism opposite to its dorsal side and, in chordates, referring to the abdomen. *See also* **dorsal**.

venule A small vein that conducts blood from capillaries to larger veins.

versus In contrast to.

vertical transmission The transmission of an agent, such as an infectious agent, from parent to offspring. *See also* **horizontal transmission**.

vesicle (adj., **vesicular**) A structure, usually within the cell cytoplasm, that is composed of a lipid bilayer that surrounds and encloses an interior lumen and that is used to transport various biomolecules to various destinations inside and outside a cell. As examples, cytoplasmic vesicles may be generated by endocytosis and soluble proteins may be exported by a cell through the exocytosis of cytoplasmic vesicles.

viability Referring to the state of a cell or organism that enables its continued survival.

vicious cycle Term used to describe the self-perpetuating, complex interactions between disseminated cancer cells, osteoclasts, and osteoblasts that has been used to explain the mechanisms underlying osteolytic metastases.

villus (pl., **villi**) Fingerlike structure that is covered by epithelial enterocytes and protrudes from the wall of the small intestine into its lumen.

vimentin Intermediate filament protein of the cytoskeleton of mesenchymal cells such as fibroblasts.

viremia Presence of high concentrations of virus in the bloodstream.

virion Virus particle including a capsid (coat) and the viral genome.

virulent Referring to an infectious agent, such as a virus, that exhibits toxicity and creates damage in an infected host cell or organism. *See also* **temperate**.

virus stock A solution of virus particles used experimentally to infect cells or organisms.

vital dye Dye that can be used to stain living cells or tissues and is retained for extended periods of time in these objects without compromising viability.

vitiligo A skin disorder, often of autoimmune origin, that leads to loss of patches of melanocytes from the epidermis and resulting loss of pigmentation.

volcano plot Convention of graphing in which the individual data points of a large data set are plotted in two dimensions; individual data points are located by the statistical significance (p-value) of the measured value data points indicated on the ordinate (*y*-axis) versus extent of measured change from a reference data set on the abscissa (*x*-axis). Both axes are usually

presented as the logarithm of the values indicated and both positive and negative values of extent of change are indicated to the right or left of the graph, respectively. *See also* **p value**.

vulnerability Property of a tumor or tumor cell that reflects its responsiveness to a specific type of cytostatic or cytotoxic therapy.

Warburg effect *See* **aerobic glycolysis**.

waterfall plot Convention of graphing the responses of individual patients to a treatment protocol by depicting each patient's response as a bar that extends either above or below the abscissa indicating ongoing growth or shrinkage in the measured size of a tumor, respectively; by convention, lower to higher patient responses to a therapy are plotted left to right on these graphs.

Western blot Procedure whereby proteins are resolved by gel electrophoresis and transferred to a filter, whereupon they are detected by incubation with appropriate monoclonal antibodies. *Also termed* **immunoblot.** *See also* **Southern blot**, **Northern blot**.

whole-exome sequencing Method used to determine the nucleotide sequence primarily of the exonic (including protein-encoding) regions of genomic DNA sample.

wild type The allele of a gene that is commonly present in the great majority of individuals in a species and is usually presumed to be fully functional.

writer An enzyme that adds covalent modifications to histones within nucleosomes, thereby regulating processes such as transcription, DNA repair, and further histone modification. *See also* **eraser**, **reader**.

xenobiotic (n., adj.) A chemical species that originates outside of the body of an organism and is foreign to its normal metabolism.

xenograft A normal or neoplastic tissue derived from one species that has been implanted into a host animal from another species.

xenotropic Referring to a class of retroviruses from one species that can infect and replicate in cells of another species.

xeroderma pigmentosum Syndrome resulting from an inherited inability to repair UV-induced DNA lesions in the skin, resulting in severe burning of the skin following exposure to sunlight and the development of skin cancers at a high rate.

zinc finger A protein structural domain that binds and is stabilized by one or more zinc ions. Zinc fingers are employed by certain transcription factors to recognize and bind specific oligonucleotide sequences in DNA.

zygote The cell created by the fusion of sperm and egg.

zymogen An inactive precursor form of an active enzyme.

zymogram Analytic technique in which the migration rates of various proteins upon gel electrophoresis are gauged by their localized enzymatic activity following such electrophoresis.

OceanofPDF.com

Index

NOTE: Numerical and symbolic prefixes have been ignored in sorting. Thus 3-MC (3-methylcholanthrene) appears at ‘mc’. Where ambiguity remains after the first hyphen, as in ‘14-3-3σ protein’ the entry is sorted as though spelled out, in this case at ‘fourteen’. Among the page references, the suffixes F, S and T indicate that the topic is covered in a Figure, Sidebar or Table only on that page. Non-text material on a page where the text is already suitably indexed is not distinguished. Italics and the prefix SS indicate coverage in a Supplementary Sidebar (the number provided is the Supplementary Sidebar number). Supplementary Sidebars are available at the end of each chapter in the ebook format of the textbook only.

Supplementary Sidebar 11.11 Why do pediatric tumors carry so few mutant driver genes? 111
Supplementary Sidebar 11.12 The gut microbiome functions as a tumor-promoting mechanism 112
Supplementary Sidebar 11.13 Experimentally induced inflammation in the liver drives tumorigenesis 113
Supplementary Sidebar 11.14 Evidence supporting the key role of COX-2 and PGE2 in the tumor-promoting inflammatory response 115
Supplementary Sidebar 12.1 Hematopoiesis is a model for the organization of many kinds of tissues 119
Supplementary Sidebar 12.2 Oxidation products in urine provide an estimate of the rate of ongoing damage to the cellular genome 121
Supplementary Sidebar 12.3 How does red meat cause colon cancer? 122

Supplementary Sidebar 12.4 Allelic variation in genes encoding metabolic enzymes can affect cancer susceptibility and response to therapy 123
Supplementary Sidebar 12.5 Oxidation removes methyl groups from DNA bases 124
Supplementary Sidebar 12.6 Following base excision repair, DNA is restored by a series of steps 125
Supplementary Sidebar 12.7 A convergence of bacterial, yeast, and human genetics led to the discovery of hereditary non-polyposis colon cancer genes 126
Supplementary Sidebar 12.8 Homology-directed repair requires a homologous sequence 127
Supplementary Sidebar 12.9 BRCA1 has diverse functions 129
Supplementary Sidebar 12.10 HPV deregulates centrosome number and induces aneuploidy 130
Supplementary Sidebar 12.11 Rare alterations in genes encoding chromatid assembly and separation proteins in tumorigenesis 131
Supplementary Sidebar 12.12 Breast cancer studies indicate that common cancers are often caused by inherited defects in caretaker genes 132
Supplementary Sidebar 13.1 Localization of growth factors is important for proper heterotypic interactions 133
Supplementary Sidebar 13.2 Heterotypic signaling in carcinomas is an ongoing process 134
Supplementary Sidebar 13.3 Certain highly advanced tumors provide exceptions to the generally observed dependence of carcinoma cells on stroma 135
Supplementary Sidebar 13.4 Heterotypic signals provoke an EMT 136
Supplementary Sidebar 13.5 Myofibroblasts predict clinical progression of cancer 137
Supplementary Sidebar 13.6 Alternative mechanisms incite neoangiogenesis 138
Supplementary Sidebar 13.7 Microvessel leakiness dooms many forms of anti-cancer therapy: optimizing anti-angiogenic VEGF-neutralizing treatment was discovered as a factor that promoted blood

vessel permeability and initially was termed vascular permeability factor (VPF) 140
Supplementary Sidebar 13.8 Angiogenesis is normally suppressed by physiological inhibitors 143
Supplementary Sidebar 13.9 Natural angiogenesis inhibitors may be employed in various forms of anti-angiogenic therapy 146
Supplementary Sidebar 13.10 Do the effects of radiotherapy depend on damaging tumor-associated microvessels? 147
Supplementary Sidebar 13.11 Fibroblasts are heterogeneous and can change dynamically in response to signals 149
Supplementary Sidebar 14.1 An example of an EMT relatively late in embryonic development 151
Supplementary Sidebar 14.2 TGF-β works in conflicting ways during tumor progression 152
Supplementary Sidebar 14.3 Signals operate in various combinations during embryogenesis 153
Supplementary Sidebar 14.4 The epithelial versus mesenchymal status of carcinoma cells appears to be influenced by cell-intrinsic responses 154
Supplementary Sidebar 14.5 Metastasizing cancer cells often take on hitchhikers while traveling through the blood 156
Supplementary Sidebar 14.6 Metastatic dissemination of advanced primary tumor cells occurs relatively rapidly 159
Supplementary Sidebar 14.7 Our cells devote an enormous number of genes to regulating protein degradation 160
Supplementary Sidebar 14.8 Complex subcellular structures enable cell motility 161
Supplementary Sidebar 14.9 Small G proteins govern cell motility 162
Supplementary Sidebar 14.10 Instruments for detecting circulating tumor cells 165
Supplementary Sidebar 14.11 Hidden micrometastases are revealed through organ transplantation 167
Supplementary Sidebar 14.12 Peritoneovenous shunts provide dramatic support for the seed-and-soil hypothesis 168
Supplementary Sidebar 14.13 Tooth extractions may occasionally become exceedingly painful 169

Supplementary Sidebar 14.14 Tumor stem cells further complicate our understanding of the metastatic process 170
Supplementary Sidebar 14.15 Does Darwinian evolution accommodate metastasis-specific alleles? 171
Supplementary Sidebar 15.1 Antibody and T-cell receptor diversity are generated by somatic rearrangement of germ-line genes 172
Supplementary Sidebar 16.1 How to make monoclonal antibodies 174
Supplementary Sidebar 16.2 Indicators of success or failure of immune checkpoint blockade therapies 177
Supplementary Sidebar 17.1 Modern cancer therapies have had only a minor effect on the overall death rate from the disease 178
Supplementary Sidebar 17.2 Clinical practice and our understanding of disease pathogenesis have often been poorly aligned, leading to sub-optimal, often tragic outcomes 179
Supplementary Sidebar 17.3 The ability to assign tumors to specific disease subtypes is critical to the success of drug development 181
Supplementary Sidebar 17.4 Prostate cancers usually do not require aggressive intervention—a tale of two countries 182
Supplementary Sidebar 17.5 *p53* germ-line polymorphisms and somatic mutations can complicate the induction of apoptosis by drugs 183
Supplementary Sidebar 17.6 Chemical synthesis, compound libraries, and high-throughput screening can identify lead compounds for further clinical development 185
Supplementary Sidebar 17.7 Evolution can generate huge collections of structurally similar proteins 187
Supplementary Sidebar 17.8 Large-scale screening can systematically interrogate the inhibitory effects of a drug on many kinases 189
Supplementary Sidebar 17.9 Epidermal growth factor receptor expression levels predict little about a tumor’s susceptibility to receptor antagonists 191
Supplementary Sidebar 17.10 BH3 profiling can measure a cell’s propensity to undergo apoptosis in response to therapy 192
